This Preface contains the following sections:

- **Purpose**
- **Audience**
- **Organization**
- **Using this manual**
- **Typographical conventions**
- **Examples of syntax descriptions**
- **Example procedures**
- **OpenEdge messages**
- **Third party acknowledgements**
Purpose

This book describes ABL (Advanced Business Language), which is the OpenEdge® programming language for building business applications. It covers all ABL statements, functions, phrases, operators, preprocessor directives, special symbols, widgets, handles, classes, interfaces, attributes, methods, properties, and events.

Audience

This book is intended for programmers who develop applications using ABL and for anyone who needs to read and understand ABL code.

Organization

This book consists of the following sections:

- A dictionary of ABL statements, functions, phrases, operators, preprocessors, and special symbols.
- A dictionary of ABL widgets.
- A dictionary of ABL handles.
- A dictionary of ABL attributes and methods (for handles).
- A dictionary of ABL handle-based object events.
- A dictionary of ABL classes and interfaces.
- A dictionary of ABL properties and methods (for classes).
- A dictionary of ABL class events and event methods
- An index of ABL keywords.

Using this manual

OpenEdge provides a special purpose programming language for building business applications. In the documentation, the formal name for this language is ABL (Advanced Business Language). With few exceptions, all keywords of the language appear in all UPPERCASE, using a font that is appropriate to the context. All other alphabetic language content appears in mixed case.

For the latest documentation updates see the OpenEdge Product Documentation Overview page on PSDN: http://communities.progress.com/pcom/docs/DOC-16074.
References to ABL compiler and run-time features

ABL is both a compiled and an interpreted language that executes in a run-time engine. The documentation refers to this run-time engine as the *ABL Virtual Machine (AVM)*. When the documentation refers to ABL source code compilation, it specifies *ABL* or *the compiler* as the actor that manages compile-time features of the language. When the documentation refers to run-time behavior in an executing ABL program, it specifies *the AVM* as the actor that manages the specified run-time behavior in the program.

For example, these sentences refer to the ABL compiler’s allowance for parameter passing and the AVM’s possible response to that parameter passing at run time: “ABL allows you to pass a dynamic temp-table handle as a static temp-table parameter of a method. However, if at run time the passed dynamic temp-table schema does not match the schema of the static temp-table parameter, the AVM raises an error.” The following sentence refers to run-time actions that the AVM can perform using a particular ABL feature: “The ABL socket object handle allows the AVM to connect with other ABL and non-ABL sessions using TCP/IP sockets.”

References to ABL data types

ABL provides built-in data types, built-in class data types, and user-defined class data types. References to built-in data types follow these rules:

- Like most other keywords, references to specific built-in data types appear in all **UPPERCASE**, using a font that is appropriate to the context. No uppercase reference ever includes or implies any data type other than itself.
- Wherever *integer* appears, this is a reference to the INTEGER or INT64 data type.
- Wherever *character* appears, this is a reference to the CHARACTER, LONGCHAR, or CLOB data type.
- Wherever *decimal* appears, this is a reference to the DECIMAL data type.
- Wherever *numeric* appears, this is a reference to the INTEGER, INT64, or DECIMAL data type.

References to built-in class data types appear in mixed case with initial caps, for example, Progress.Lang.Object. References to user-defined class data types appear in mixed case, as specified for a given application example.

Structure of reference entries

Each ABL element reference description includes some subset of the following information:

- Platform-restriction notations
- A purpose or description of the language element
- Block properties for all block statements
- Data-movement diagrams for all data-handling statements
- The syntax for the language element
- The options and arguments you can use with the language element
• One or more examples that illustrate the use of the language element
• Notes that highlight special cases or provide hints on using the language element
• A See Also section that lists related language elements

Platform-restriction notes

Some language elements and features of ABL do not apply to all software platforms—operating systems, user interfaces, and database management systems—that OpenEdge supports. The documentation tries to note each such platform restriction with the language element title. Some language elements apply to SpeedScript programming and some do not; the documentation indicates which language elements do not apply with a note in the language element description.

You can consider a language element as supported for all interfaces, on all operating systems, and for SpeedScript unless otherwise indicated in the language element description.

The platform restriction notes that appear in the documentation include the following:

• **AppServer™ only**
  The element or feature applies only to the OpenEdge AppServer.

• **Character interfaces only**
  The element or feature applies only to the character interfaces that OpenEdge supports.

• **Graphical interfaces only**
  The element or feature applies only to the graphical interfaces that OpenEdge supports.

• **NT and UNIX only**
  The element or feature applies only to the Windows and UNIX versions that OpenEdge supports.

• **ORACLE only**
  The element or feature applies only to the ORACLE versions that OpenEdge supports.

• **UNIX only**
  The element or feature applies only to the UNIX versions that OpenEdge supports.

• **Windows only**
  The element or feature applies only to the Windows versions that OpenEdge supports.

• **Windows only; Graphical interfaces only**
  The element or feature applies only to the graphical interfaces of the traditional OpenEdge GUI for the Windows versions that OpenEdge supports.

• **Windows only; GUI for .NET only**
  The element or feature applies only to the .NET forms, controls, or other .NET objects for the Windows versions that OpenEdge supports.
For a complete list of the software platforms that OpenEdge supports, see *OpenEdge Getting Started: Installation and Configuration*.

**Typographical conventions**

This manual uses the following typographical conventions:

<table>
<thead>
<tr>
<th>Convention</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Bold</strong></td>
<td>Bold typeface indicates commands or characters the user types, provides emphasis, or the names of user interface elements.</td>
</tr>
<tr>
<td><em>Italic</em></td>
<td>Italic typeface indicates the title of a document, or signifies new terms.</td>
</tr>
<tr>
<td><strong>SMALL, BOLD CAPITAL LETTERS</strong></td>
<td>Small, bold capital letters indicate OpenEdge key functions and generic keyboard keys; for example, <em>GET</em> and <em>CTRL</em>.</td>
</tr>
<tr>
<td><strong>KEY1+KEY2</strong></td>
<td>A plus sign between key names indicates a <em>simultaneous</em> key sequence: you press and hold down the first key while pressing the second key. For example, <em>CTRL+X</em>.</td>
</tr>
<tr>
<td><strong>KEY1 KEY2</strong></td>
<td>A space between key names indicates a <em>sequential</em> key sequence: you press and release the first key, then press another key. For example, <em>ESCAPE H</em>.</td>
</tr>
</tbody>
</table>

**Syntax:**

- **Fixed width**
  A fixed-width font is used in syntax statements, code examples, system output, and filenames.

- **Fixed-width italics**
  Fixed-width italics indicate variables in syntax statements.

- **Fixed-width bold**
  Fixed-width bold indicates variables with special emphasis.

- **UPPERCASE fixed width**
  Uppercase words are ABL keywords. Although these are always shown in uppercase, you can type them in either uppercase or lowercase in a procedure.

- **[]**
  Large brackets indicate the items within them are optional.

- **[]**
  Small brackets are part of ABL.

- **{}**
  Large braces indicate the items within them are required. They are used to simplify complex syntax diagrams.
Examples of syntax descriptions

In this example, ACCUM is a keyword, and aggregate and expression are variables:

Syntax

```
ACCUM aggregate expression
```

FOR is one of the statements that can end with either a period or a colon, as in this example:

```
FOR EACH Customer:
    DISPLAY Name.
END.
```

In this example, STREAM stream, UNLESS-HIDDEN, and NO-ERROR are optional:

Syntax

```
DISPLAY [ STREAM stream ] [ UNLESS-HIDDEN ] [ NO-ERROR ]
```

In this example, the outer (small) brackets are part of the language, and the inner (large) brackets denote an optional item:

Syntax

```
INITIAL [ constant [, constant ] ]
```

A called external procedure must use braces when referencing compile-time arguments passed by a calling procedure, as shown in this example:

Syntax

```
{ &argument-name }
```
In this example, EACH, FIRST, and LAST are optional, but you can choose only one of them:

**Syntax**

\[
\text{PRESELECT \ [ \text{EACH} \ | \text{FIRST} \ | \text{LAST} \ ] \ record-phrase}
\]

In this example, you must include two expressions, and optionally you can include more. Multiple expressions are separated by commas:

**Syntax**

\[
\text{MAXIMUM ( expression , expression [ , expression ] . . . )}
\]

In this example, you must specify MESSAGE and at least one expression or SKIP \([n]\), and any number of additional expression or SKIP \( [n] \) is allowed:

**Syntax**

\[
\text{MESSAGE \{ expression \| \text{SKIP [ ( n ) ]} \} . . .}
\]

In this example, you must specify \{include-file, then optionally any number of argument or \&argument-name = "argument-value", and then terminate with \}:

**Syntax**

\[
\{ \text{include-File}
\begin{array}{l}
\text{ [ argument \| \&argument-name = "argument-value" ] . . .}
\end{array}
\}
\]

### Long syntax descriptions split across lines

Some syntax descriptions are too long to fit on one line. When syntax descriptions are split across multiple lines, groups of optional and groups of required items are kept together in the required order.

In this example, WITH is followed by six optional items:

**Syntax**

\[
\text{WITH \ [ \text{ACCUM max-length} \ ] \ [ expression \text{ DOWN} \ ]}
\begin{array}{l}
\text{ [ CENTERED ] \ [ n \text{ COLUMNS} ] \ [ \text{SIDE-LABELS} ]}
\end{array}
\text{ [ STREAM-IO ]}
\]
Complex syntax descriptions with both required and optional elements

Some syntax descriptions are too complex to distinguish required and optional elements by bracketing only the optional elements. For such syntax, the descriptions include both braces (for required elements) and brackets (for optional elements).

In this example, ASSIGN requires either one or more field entries or one record. Options available with field or record are grouped with braces and brackets:

Syntax

\[
\text{ASSIGN} \quad \{ \quad \text{FRAME frame} \quad \} \{ \quad \text{field} \quad [ = \text{expression} ] \quad \}\quad \text{WHEN} \quad \text{expression} \quad \}\quad \ldots \\
\quad \{ \quad \text{record} \quad [ \text{EXCEPT} \quad \text{field} \quad \ldots \quad ] \quad \} \\
\]

Example procedures

This manual provides numerous example procedures that illustrate syntax and concepts. You can access the example files and details for installing the examples from the following locations:

- The Documentation and Samples located in the doc_samples directory on the OpenEdge Product DVD
- The OpenEdge Product Documentation Overview page on PSDN:

  http://communities.progress.com/pcom/docs/DOC-16074

Once installed, you can locate the example files for this manual in the following OpenEdge installation directory path:

src\prodoc\langref
OpenEdge displays several types of messages to inform you of routine and unusual occurrences:

- **Execution messages** inform you of errors encountered while OpenEdge is running a procedure; for example, if OpenEdge cannot find a record with a specified index field value.

- **Compile messages** inform you of errors found while OpenEdge is reading and analyzing a procedure before running it; for example, if a procedure references a table name that is not defined in the database.

- **Startup messages** inform you of unusual conditions detected while OpenEdge is getting ready to execute; for example, if you entered an invalid startup parameter.

After displaying a message, OpenEdge proceeds in one of several ways:

- Continues execution, subject to the error-processing actions that you specify or that are assumed as part of the procedure. This is the most common action taken after execution messages.

- Returns to the Procedure Editor, so you can correct an error in a procedure. This is the usual action taken after compiler messages.

- Halts processing of a procedure and returns immediately to the Procedure Editor. This does not happen often.

- Terminates the current session.

OpenEdge messages end with a message number in parentheses. In this example, the message number is 200:

```
** Unknown table name table. (200)
```

If you encounter an error that terminates OpenEdge, note the message number before restarting.

**Obtaining more information about OpenEdge messages**

In Windows platforms, use OpenEdge online help to obtain more information about OpenEdge messages. Many OpenEdge tools include the following Help menu options to provide information about messages:

- Choose **Help → Recent Messages** to display detailed descriptions of the most recent OpenEdge message and all other messages returned in the current session.

- Choose **Help → Messages** and then type the message number to display a description of a specific OpenEdge message.

- In the Procedure Editor, press the **HELP** key or **F1**.

On UNIX platforms, use the OpenEdge pro command to start a single-user mode character OpenEdge client session and view a brief description of a message by providing its number.
To use the pro command to obtain a message description by message number:

1. Start the Procedure Editor:

   ```
   OpenEdge-install-dir/bin/pro
   ```

2. Press F3 to access the menu bar, then choose Help → Messages.

3. Type the message number and press ENTER. Details about that message number appear.

4. Press F4 to close the message, press F3 to access the Procedure Editor menu, and choose File → Exit.

ABL Reference

This section contains reference entries that describe the syntax of ABL. They begin with
descriptions of the language punctuation and special characters. The remaining entries contain
descriptions of the ABL statements, functions, phrases, preprocessor directives, and
miscellaneous other language elements.

You can consider a language element as supported for all interfaces, on all operating systems,
and for SpeedScript unless otherwise indicated in each language element description. These
descriptions refer to both compile-time and run-time behavior, features that the language
generally supports and determines at compile time and actions directed by using these features
at run time. When describing compile-time features or actions, this section references ABL or
the ABL compiler. When describing ABL-directed actions taken at run time, this section
references the ABL Virtual Machine (AVM).

: Punctuation

The colon (:) symbol ends block labels and block header statements like DO, FOR, and
REPEAT. It also serves as a separator between:

- A handle reference and an attribute or method, for example ttCust:PRIVATE-DATA or
ttCust:CLEAR( ), where ttCust is a handle to a temp-table

- An object or static type-name reference and a class-based property, method, or event, for
example, rObj:ToString( ), rObj:NEXT-SIBLING, or Progress.Lang.Class:GetClass(
  "Progress.Data.BindingSource" ), where rObj is an object reference to a
  Progress.Lang.Object instance

- A character string literal and one of its options, for example, "City/State/Zip":Ü

It also follows the EDITING keyword in an EDITING phrase and is a device delimiter in
Windows.
See :: Punctuation for rules to help you decide whether to use period, colon, or double colon syntax.

See also :: Punctuation, . Punctuation, "Character-string literal, Class-based object reference, Type-name syntax

:: Punctuation

The double colon (::) is a short-hand syntax for referencing constant named members of database object containers, for example dynamic ProDataSets, queries, temp-tables, and buffers.

The following rules will help you to decide whether to use dot, colon, or double colon syntax:

• Use a dot between two names when the left-hand side name is the actual name of a database or table, known at compile time, and is not a handle or reference of any kind. For example, Customer.CustNum or Sports2000.Customer or Sports2000.Customer.CustNum.

• Use a colon between two character strings when the left-hand side is a handle or reference, and is not the actual name of a database or table, and the right-hand side is an attribute or method for the left-hand-side handle or reference. For example, hBuff:NUM-FIELDS, or hDset:NUM-BUFFERS or hBuff:FIND-FIRST.

• Use a double colon between two character strings when the left-hand side name is a handle to a container object of some kind (buffer, table or ProDataSet) and the right-hand side is not an attribute or method, but instead is a named member of the left-hand side. For example, hBuff::CustNum or hDset::Customer or hDset::Customer::CustNum.

For example, if hBuff is a HANDLE to the Customer table, then hBuff:NAME returns the string "Customer", but hBuff::NAME returns the value of the NAME field for the current record in the hBuff Buffer, e.g. "Lift Line Skiing".

See also :: Punctuation, . Punctuation

. Punctuation

The period (.) symbol ends all statements, including block header statements. The DO, FOR, and REPEAT statements can end with a period or a colon.

It is also serves as a separator between:

• A filename and a filename extension (suffix) in most operating system platforms, for example, Letter.txt

• The elements of a qualified database table or buffer field name, for example, Customer.CustNum or Sports2000.Customer or Sports2000.Customer.CustNum

• The elements of an ABL package name or .NET namespace, for example, Progress.Lang, Progress.Windows, or System.Collections
• An ABL package or .NET namespace and the name of a class or interface defined in that
package or namespace, for example, Progress.Lang.Error, Progress.Windows.Form, or
System.Collections.SortedList

See :: Punctuation for rules to help you decide whether to use period, colon, or double colon
syntax.

See also : Punctuation, :: Punctuation, Type-name syntax

; Punctuation

In Progress® Version 6.0 or later, the ANSI SQL (-Q) startup parameter allows you to redefine
the semicolon as a terminator. This startup parameter enforces strict ANSI SQL conformance
and allows you to terminate SQL statements with a semicolon. The ANSI SQL (-Q) parameter
allows OpenEdge® to run standard SQL statements and scripts built with other products.

The ANSI SQL (-Q) parameter disables the use of the semicolon within UNIX escapes.

UNIX SMBL=foo; export SMBL

As a general rule, use the period (.) as a terminator for ABL statements even when you specify
the ANSI SQL (-Q) parameter for an ABL session.

, Punctuation

The comma (,) symbol separates multiple file specifications (used in FOR statements, FOR
phrases of DO and REPEAT statements, and PRESELECT phrases), branching statements
(used in UNDO statements and phrases), and multiple arguments of a function.

; Special character

This special character is supported only for backward compatibility.

The semicolon (;), when combined with a second character in the Procedure Editor, provides
alternative representations of special characters as follows:

<table>
<thead>
<tr>
<th>Special Character</th>
<th>@</th>
<th>[</th>
<th>]</th>
<th>^</th>
<th>`</th>
<th>{</th>
<th>}</th>
<th>~</th>
</tr>
</thead>
<tbody>
<tr>
<td>Alternative</td>
<td>; &amp;</td>
<td>;&lt;</td>
<td>;&gt;</td>
<td>;*</td>
<td>;'</td>
<td>;(</td>
<td>;%</td>
<td>;)</td>
</tr>
</tbody>
</table>

To suppress the semicolon’s interpretation as a special character, precede it with a tilde (~). For
example, to enter the string ;< in the Procedure Editor and not have ABL interpret it as an open
bracket, type ~;<.
Additionally, if an ASCII character is mapped to an extended alphabetical character by an IN statement in the PROTERMCAP file, you can enter the extended character in the Procedure Editor by preceding the ASCII character with a semicolon. For example, if [ is mapped to Å, ABL interprets the ;[ sequence as Å.

**Special character**

The question mark is a special character that represents the Unknown value. ABL treats a quoted question mark ("?") in a procedure or an input field as a question mark character. It treats an unquoted question mark (?) in a procedure or an input field as an unknown value.

Table 1 indicates the results when using the Unknown value (?) in a comparison expression (EQ, GE, GT, LE, LT, NE). These results are true for both character and integer variables.

**Table 1: Using the Unknown value (?) in comparison operations**

<table>
<thead>
<tr>
<th>Comparison operator</th>
<th>One argument is ?</th>
<th>Both arguments are ?</th>
</tr>
</thead>
<tbody>
<tr>
<td>EQ or =</td>
<td>F</td>
<td>T</td>
</tr>
<tr>
<td>GE or &gt;=</td>
<td>?</td>
<td>T</td>
</tr>
<tr>
<td>GT or &gt;</td>
<td>?</td>
<td>F</td>
</tr>
<tr>
<td>LE or &lt;=</td>
<td>?</td>
<td>T</td>
</tr>
<tr>
<td>LT or &lt;</td>
<td>?</td>
<td>F</td>
</tr>
<tr>
<td>NE or &lt;&gt;</td>
<td>T</td>
<td>F</td>
</tr>
</tbody>
</table>

**Note:** WebSpeed® treats an unquoted question mark (?) in an HTML input field as a character.

Additional points about the Unknown value (?) are:

- Any number of Unknown value (?) records can be in a unique index. This is useful in cases where you want to defer choosing key values for a unique index.

- If you define a field as mandatory in the Dictionary, that field cannot contain the Unknown value (?) when the AVM writes the record to the database.

- For sorting and indexing purposes, the Unknown value (?) sorts high.

- The question mark (?) character in the first position of a field equals the Unknown value (?), not a question mark.

- When using the Unknown value (?) in a comparison expression for SQL, the result is unknown.

- When using the Unknown value (?) in an expression, the result of that expression is usually unknown. For example, when you concatenate first, middle, and last names, and the middle name is ?, then the result is ?.
For information on how the Unknown value (?) works with logical data types, comparison operators, and conditional statements, see the following reference entries: EQ or = operator, GE or >= operator, GT or > operator, IF...THEN...ELSE statement, LE or <= operator, LT or < operator, NE or <> operator

\ Special character

The backslash (\) is an escape character on UNIX platforms only. It is a directory path separator in Windows platforms only.

~ Special character

The tilde (~) is an escape character that causes the AVM to read the following character literally. A tilde followed by three octal digits represents a single character. Use it as a lead-in to enter the special characters shown in Table 2. In a procedure, a tilde followed by something other than the items in Table 2 is ignored. For example, "~abc" is treated as "abc". (This may not work as expected when passing parameters to an include file.) The items in Table 2 are case sensitive.

<table>
<thead>

</tbody>
</table>
" Special character

The double quote (") encloses character constants or strings. To use quotes within a quoted character string, you must use two double quotes (""), which compile to a single double quote ("), or you must put a tilde (~) in front of any quotes within the quoted character string. (This does not work when passing parameters to an include file.)

See also  " "Character-string literal

' Special character

The function of the single quote (') is the same as the double quote. But, if you use single and double quotes in a statement, the compiler checks the outermost quotes first, giving them precedence over the innermost quotes. For example, DISPLAY '"test"' shows up as "test", (ABL reads the double quotes literally), and DISPLAY "'test2'" shows up as 'test2'.

See also  " "Character-string literal

/ Special character

The slash (/) symbol is a directory path separator (UNIX). It is also used for date fields (99/99/99).

See also  " "Character-string literal

( ) Expression precedence

Parentheses raise expression precedence. Also, some functions require you to enclose arguments in parentheses.

See also  / Division operator, Expression

[ ] Array reference

Square brackets ([ ]) enclose array subscripts ([1], [2], etc.) or ranges (such as, [1 FOR 4]). In a range, you can use a variable for the first element, but the second element must be a constant. The specification [1 FOR 4] causes ABL to start with the first array element and to work with that and the next three elements. Square brackets are also used when specifying initial values for an array. For example, if you define an array variable of extent 3, you might specify initial values as INITIAL [0, 1, 2].

= Special character

See the “EQ or = operator”, “Assignment (=) statement”.

< Special character

See the “LT or < operator”.

<= Special character

See the “LE or <= operator”.

<> Special character

See the “NE or <> operator”.

> Special character

See the “GT or > operator”.

>= Special character

See the “GE or >= operator”.

" "Character-string literal

Specifies a literal character-string value.

Syntax

"characters" [ : [ R | L | C | T ] ] [ U ] [ max-length ] ]

characters

The literal contents of the character string.

R | L | C | T

Specifies the justification of the string within its maximum length: right, left, centered, or trimmed, respectively. The default justification depends on how the string is used. If the string is displayed with side labels, the default is right justification. If column labels are used, the defaults are left justification for character fields and right justification for numeric fields. Strings used in expressions are trimmed by default.

• R means right justified and padded on the left with spaces: "Hello";R10 = "Hello".

• L means left justified and padded on the right with spaces: "Hello";L10 = "Hello ".

• C means centered within the string and padded on both the right and left as needed:

"Hello":C10 = " Hello ".

• T means trimmed of leading and trailing blanks (although storage space and screen space is still allocated for the maximum number of characters): 

" Hello":T10 = "Hello" (but screen and storage space is still reserved for 10 characters).

U

Specifies that the string is untranslatable. This means that the string will not be processed by the OpenEdge Translation Manager. If you do not specify U, then the string is assumed to be translatable.

max-length

The number of characters reserved for the string contents in the text segment. The default is the length of the string itself. You might want to specify a longer length if you expect a translation of the string to be longer. The longest length you can specify is 5120 characters.

Note

If you include the colon (:) after the quoted string, you must supply at least one option. Otherwise, ABL treats the colon as a statement separator.

} Argument reference

References the value of an argument that a procedure passes to a called external procedure file or to an include file.

ABL converts each argument to a character format. This conversion removes the surrounding double-quotes if the parameter was specified as a character string constant in the RUN statement or include file reference.

When one procedure is called from another and arguments are used, ABL recompiles the called procedure, substituting the arguments that the calling procedure passes, and then runs the called procedure.

Syntax

\{
  \{ n | &argument-name \}
\} 

Enter the braces (\{\}) as shown; they do not represent syntax notation in this description.

n

The number of the argument being referred to. If \( n = 0 \), ABL substitutes the name of the current procedure (the name you used when you called it, not the full pathname) as the argument. If \( n = * \), ABL substitutes all arguments that the calling procedure passes (but not the name \{0\}). If you refer to the \( n \)th parameter and the calling procedure does not supply it, \{n\} is ignored.

&argument-name

The name of the argument being referred to. If you refer to an argument-name and the calling procedure does not supply it, ABL ignores \{&argument-name\}. 
If argument-name is an asterisk (*), ABL substitutes all arguments that the calling procedure passes. It also adds quotation marks to each parameter, so you can pass the named argument list through multiple levels of include files.

**Note:** It is invalid to pass both numbered and named arguments within a single pair of braces. Although this will not cause a compile-time or run-time error, the arguments will not be passed correctly.

### Examples

The procedure `r-arg.p` runs procedure `r-arg2.p`, passing the arguments customer and name to `r-arg2.p`. ABL substitutes these arguments for `{1}` and `{2}` in the `r-arg2.p` procedure.

**r-arg.p**

```plaintext
RUN r-arg2.p "customer" "name"
```

**r-arg2.p**

```plaintext
FOR EACH {1}:
   DISPLAY {2}.
END.
```

The `r-inc.p` procedure defines the variables `txt` and `num`, and assigns the values "Progress VERSION" and "7" to them. The `r-inc.p` procedure includes the `r-inc.i` file and passes the `&int` and `&str` arguments to the include file. Because the parameters are named, their order is unimportant. The called procedure can find each argument, regardless of placement. The `r-inc.i` include file displays a message that consists of the passed arguments. The asterisk argument displays all the parameters as they are listed in the `r-inc.p` procedure.

**r-inc.p**

```plaintext
DEFINE VARIABLE cTxt AS CHARACTER NO-UNDO.
DEFINE VARIABLE iNum AS INTEGER NO-UNDO.
ASSIGN
   cTxt = "Progress VERSION"
   iNum = 7.
{r-inc.i &int=iNum &str=cTxt}
```

**r-inc.i**

```plaintext
MESSAGE {&str} /* the &str named argument */
{&int}. /* the &int named argument */
MESSAGE "An asterisk displays all the arguments:"
[*] /* all the arguments passed by the calling procedure */
```

### Notes

- If you pass `{}` arguments using the RUN statement, you cannot precompile the called procedure. When ABL compiles a procedure, it must have all the values the procedure needs. So, if you pass arguments to a procedure you are calling with the RUN statement, the AVM evaluates those arguments when the calling procedure is run, not when it is compiled.
• You can use the name of an include file as an argument to another include file. For example, a reference to \{1\} in an included procedure causes ABL to include the statements from the file with the name that passed as the first argument.

• Use DEFINE PARAMETER to define a run-time parameter in a called subprocedure. Each parameter requires its own DEFINE statement. The parameters must be specified in the RUN statement in the same order as defined with DEFINE statements.

• ABL disregards an empty pair of braces ({}).

• The maximum length of the arguments you can pass to an include file is determined by the Input Characters (-inp) startup parameter.

• An argument argument-name behaves like a scoped preprocessor name. Thus, if you define a preprocessor name, argument-name, its value replaces the value of any argument argument-name passed to the same file at the point where the preprocessor name, argument-name, is defined.

See also ; Special character, { } Include file reference, { } Preprocessor name reference, COMPILE statement, DEFINE PARAMETER statement, RUN statement

### { } Include file reference

Causes ABL to retrieve the statements in a file and compile them as part of the main procedure if it encounters the file’s name inside braces ({}) when compiling the procedure. You can name arguments you want substituted in the file before compilation.

**Syntax**

```
\{ include-file
[ argument ... | { &argument-name = "argument-value" } ... ] \}
```

Enter the braces ({} as shown; they do not represent syntax notation in this description.

**include-file**

The name of an external operating system file that contains statements you want included during the compilation of a main procedure. This filename follows normal operating system naming conventions and is case sensitive on UNIX. If the file you name has an unqualified path name, ABL searches directories based on the PROPATH environment variable.

When ABL compiles the main procedure (the procedure containing the { } include file reference), it copies the contents of include-file into that procedure, substituting any arguments. So, you can use included procedures with arguments even when you precompile a procedure.

**argument**

A value used by include-file, as a positional argument.

With positional arguments, the first argument replaces \{1\} in the included file, the second argument replaces \{2\}, and so on.
A name/value pair used by include-file as a named argument. The argument-name is the name of the argument you want to pass to the include file. You can use variable names, field names, and reserved words as argument names. The argument-value is the value of the argument you pass to the include file. Enclose the argument-value in quotation marks, as shown.

With named arguments, argument-value replaces &argument-name in the included file.

**Examples**

The r-inc1.p procedure uses externally defined and maintained files (r-fcust.i and r-dcust.i) for the layout and display of a customer report. You can use these same include files in many procedures.

**r-inc1.p**

```plaintext
FOR EACH Customer NO-LOCK:
{r-fcust.i}
{r-dcust.i}
END.
```

**r-fcust.i**

```plaintext
FORM Customer.CustNum Customer.Name LABEL "Customer Name"
Customer.Phone FORMAT "999-999-9999".
```

**r-dcust.i**

```plaintext
```

The r-inc12.p example references an include file (r-show.i) that can take up to five arguments, and the main routine passes four arguments.

**r-inc12.p**

```plaintext
DEFINE VARIABLE var1 AS INTEGER NO-UNDO INITIAL 9.
DEFINE VARIABLE var2 AS DECIMAL NO-UNDO INITIAL 6.43.
DEFINE VARIABLE var3 AS LOGICAL NO-UNDO INITIAL TRUE.
/* any statements */
{r-show.i point-A var1 var2 var3}
/* any statements */
```

**r-show.i**

```plaintext
MESSAGE "At" "{1}" "{2}" "{3}" "{4}" "{5}" "{6}".
```

When the main procedure is compiled, the line referencing the r-show.i include file is replaced by the following line:

```plaintext
MESSAGE At point-A var1 9 var2 6.43 var3 yes
```
This example shows how you can use include files to extend ABL. The main procedure uses a new statement, `r-show.i`, to display the values of fields or variables at various points in a procedure. The include file in this example can handle up to five passed arguments. The main procedure only passes four (point-A, var1, var2, and var3).

The `r-custin.p` procedure displays a frame for each customer that you can update with customer information. The procedure includes `r-cstord.i` and passes the named argument `&frame-options`, and the value of the argument (CENTERED ROW 3 NO-LABEL) to the include file. When the include file references the `&frame-options` argument, it uses the value of the argument, and therefore displays the OVERLAY frame `cust-ord` as a centered frame at row 3 without a label.

### `r-custin.p`

```abl
FOR EACH Customer:
    {r-cstord.i &frame-options = "CENTERED ROW 3 NO-LABEL"}.
        Customer.CreditLimit WITH FRAME cust-ord.
END.
```

### `r-cstord.i`

```abl
FORM "Cust #" AT 1 Customer.CustNum AT 10 SKIP(1)
    Customer.Name AT 10
    customer.Address AT 10
    customer.Address2 AT 10
    customer.City AT 10 Customer.State Customer.PostalCode SKIP(1)
    "Phone " AT 1 Customer.Phone FORMAT "999/999-9999" AT 10
    "Max Crd" AT 1 Customer.CreditLimit AT 10
    WITH FRAME cust-ord OVERLAY {&frame-options}.
```

Include files are particularly useful for using form layouts in multiple procedures, especially if you do not include the keyword FORM or the closing period (.) of the FORM statement. Thus, the following `r-inc13.p` procedure includes the `r-cust.f` file as the definition of a FORM statement.

### `r-inc13.p`

```abl
FORM {r-cust.f}.
```

### `r-cust.f`

```abl
Customer.CustNum
Customer.Name SKIP(2)
Customer.State
```

The `r-inc14.p` procedure uses the same include file as a layout for a DISPLAY statement:

### `r-inc14.p`

```abl
FOR EACH Customer NO-LOCK:
    DISPLAY {r-cust.f} WITH 3 DOWN.
END.
```
Notes

- You can pass a series of positional arguments or a series of named arguments to an include file, but you cannot pass a combination of positional and named arguments to an include file.

- When you use braces to include one procedure in another, ABL does not include the second procedure until it compiles the first one. This technique has the same effect as using the Editor to copy statements into the main procedure. At times, separate include files are easier to maintain.

- You can nest include files. (They can contain references to other include files.) The number of nested include files is limited by the number of file descriptors available on the system.

- If you have many nested include files and you are running on a Sequent machine, use Maximum Files (-Mv) startup parameter to control the number of files you can open simultaneously.

- When you have a base procedure and want to make several copies of it, changing it slightly each time, use include files with parameters. For example, at times you might only want to change the name of some files or fields used by the procedure.

- If you define a preprocessor name and later pass a compile-time argument with the same name, but a different value, to a procedure or include file, the value of the initial preprocessor name remains unchanged. Thus, a compile-time argument is scoped to the file to which it is passed.

- Instead of maintaining duplicate source files, create a single include file with the variable portions (such as the names of files and fields) replaced by {1}, {2}, etc. Then each procedure you write can use that include file, passing file and field names as arguments.

- You can use the name of an include file as an argument to another include file. For example, a reference to {{1}} in an include file causes ABL to include the statements from the file with the name that passed as the first argument.

- ABL disregards an empty pair of braces ({}).

- If you use double quotes (" ") around arguments in an argument list, ABL removes them. However, if you use single quotes (' '), ABL passes them. To pass one set of double quotes, you must use four sets of double quotes.

- When ABL reads an include file into the source, it appends a space character to the end of an include file. For example, the following include file r-string.i contains data that is used by r-incstr.p.

```
r-string.i
abcde
```

```
r-incstr.p
DISPLAY LENGTH("{r-string.i}").
```

Although r-string.i contains five letters, when you run r-incstr.p, it returns the value 6 because ABL appends a space character to the end of r-string.i.
• The maximum length of the arguments you can pass to an include file is determined by the Input Characters (-inp) startup parameter.

See also { } Argument reference, { } Preprocessor name reference, COMPILE statement, DEFINE PARAMETER statement, RUN statement

{ } Preprocessor name reference

References the value of a preprocessor name in any ABL or preprocessor expression.

Syntax

```
{ &preprocessor-name }
```

Enter the braces ({} as shown; they do not represent syntax notation in this description.

{ preprocessor-name }

Expands the name, `preprocessor-name`, to its defined value. You can define preprocessor names using either the &GLOBAL-DEFINE preprocessor directive or the &SCOPED-DEFINE preprocessor directive. ABL also provides a set of built-in preprocessor names that you can reference for a variety of session information. Table 3 lists each built-in preprocessor name with its description.

**Table 3: Built-in preprocessor names (1 of 2)**

<table>
<thead>
<tr>
<th>The preprocessor name . . .</th>
<th>Expands to an unquoted string . . .</th>
</tr>
</thead>
<tbody>
<tr>
<td>BATCH-MODE</td>
<td>Equal to &quot;yes&quot; if the Batch (-b) startup parameter was used to start the client session. Otherwise, it expands to &quot;no&quot;.</td>
</tr>
<tr>
<td>FILE-NAME</td>
<td>That contains the name of the file being compiled.¹ If you want only the name of the file as specified in the { } Include File Reference, the RUN statement, or the COMPILE statement, use the argument reference {0}.</td>
</tr>
<tr>
<td>LINE-NUMBER</td>
<td>That contains the current line number in the file being compiled. If you place this reference in an include file, the line number is calculated from the beginning of the include file.</td>
</tr>
<tr>
<td>OPSYS</td>
<td>That contains the name of the operating system on which the file is being compiled. The OPSYS name can have the same values as the OPSYS function. The possible values are “UNIX” and “WIN32”.²</td>
</tr>
</tbody>
</table>

¹

²
Table 3: Built-in preprocessor names

<table>
<thead>
<tr>
<th>The preprocessor name . . .</th>
<th>Expands to an unquoted string . . .</th>
</tr>
</thead>
<tbody>
<tr>
<td>SEQUENCE</td>
<td>Representing a unique integer value that is sequentially generated each time the SEQUENCE preprocessor name is referenced. When a compilation begins, the value of {&amp;SEQUENCE} is 0; each time {&amp;SEQUENCE} is referenced, the value increases by 1. To store the value of a reference to SEQUENCE, you must define another preprocessor name as {&amp;SEQUENCE} at the point in your code you want the value retained.</td>
</tr>
<tr>
<td>WINDOW-SYSTEM</td>
<td>That contains the name of the windowing system in which the file is being compiled. The possible values include &quot;MS-WINDOWS&quot;, &quot;MS-WIN95&quot;, &quot;MS-WINXP&quot;, and &quot;TTY&quot;.</td>
</tr>
</tbody>
</table>

1. When running the source code of a procedure file loaded into the Procedure Editor or the AppBuilder, \{&FILE-NAME\} expands to a temporary filename, not the name of the file under which the source code might be saved.

2. ABL supports an override option that enables applications that need to return the value of MS-DOS for all Microsoft® operating systems to do so. For example, if you do not want the value WIN32 to be returned when either Windows 95 or Windows NT operating systems are recognized, you can override this return value by defining the Opsys key in the Startup section of the current environment, which can be in the registry or in an initialization file. If the Opsys key is located, the OPSYS function returns the value associated with the Opsys key on all platforms.

3. ABL supports an override option for the &WINDOW-SYSTEM preprocessor name that provides backward compatibility. This option enables applications that need the WINDOW-SYSTEM preprocessor name to return the value of MS-WINDOWS for all Microsoft operating systems to do so. To establish this override value, define the WindowSystem key in the Startup section of the current environment, which can be in the registry or in an initialization file. If the WindowSystem key is located, the WINDOW-SYSTEM preprocessor name returns the value associated with the WindowSystem key on all platforms.

Table 4 lists the additional built-in preprocessor names that apply to SpeedScript.

Table 4: SpeedScript built-in preprocessor names

Examples

The r-prprc1.p procedure shows how you can reference a built-in preprocessor name and include it in a character string.

r-prprc1.p

MESSAGE "The current operating system is" "{&OPSYS}."  
VIEW-AS ALERT-BOX.
The procedure r-prprc2.p shows how to capture the value of a \{&SEQUENCE\} reference. In this example, \{&SEQUENCE\} is referenced three times, once each to assign its value to wvar (0) and xvar (1) at run time. The third reference defines the preprocessor name Last-Value with the value 3. As shown, Last-Value is assigned unchanged to both yvar and zvar, each of which take the value 3 at run time.

**r-prprc2.p**

```
DEFINE VARIABLE wvar AS INTEGER NO-UNDO.
DEFINE VARIABLE xvar AS INTEGER NO-UNDO.
DEFINE VARIABLE yvar AS INTEGER NO-UNDO.
DEFINE VARIABLE zvar AS INTEGER NO-UNDO.

ASSIGN
  wvar = \{&SEQUENCE\}
  xvar = \{&SEQUENCE\}.

&GLOBAL-DEFINE Last-Value \{&SEQUENCE\}

ASSIGN
  yvar = \{&Last-Value\}
  zvar = \{&Last-Value\}.

MESSAGE "wvar =" wvar SKIP "xvar =" xvar SKIP
  "yvar =" yvar SKIP "zvar =" zvar VIEW-AS ALERT-BOX.
```

The procedure r-prprc3.p shows how preprocessor names override compile-time arguments. In this example, r-prprc3.p defines the preprocessor name My-Name as "Daniel". It then passes the compile-time argument My-Name, with the value "David", to the include file r-prprc3.i, which in turn defines a preprocessor name My-Name as "Donald".

**r-prprc3.p**

```
&SCOPED-DEFINE My-Name "Daniel"
{r-prprc3.i &My-Name = "David"}
MESSAGE "My-Name preprocessed in r-prprc3.p is" \{&My-Name\} + "."
  VIEW-AS ALERT-BOX.
```

**r-prprc3.i**

```
MESSAGE "My-Name argument in r-prprc3.i is" \{&My-Name\} + "."
  VIEW-AS ALERT-BOX.
&SCOPED-DEFINE My-Name "Donald"
MESSAGE "My-Name preprocessed in r-prprc3.i is" \{&My-Name\} + "."
  VIEW-AS ALERT-BOX
```

During execution, the first message included by r-prprc3.i displays the value of the My-Name argument, "David". The second message included by r-prprc3.i displays the value of the following My-Name preprocessor name, defined as "Donald", permanently overriding "David" passed by the My-Name argument. Finally, the message in r-prprc3.p displays the value of the My-Name preprocessor name that was initially defined there, "Daniel", because the value from My-Name established in r-prprc3.i ("Donald") went out of scope during compilation.

Note also that the reference to the My-Name compile-time argument in r-prprc3.i is inside double-quotes, because ABL passes string constant values for compile-time arguments without the surrounding double-quotes.
You can encounter compilation problems mixing preprocessor names with compile-time argument names. The following example, a variation of r-prprc3.i, does not compile, even when passed a My-Name argument as an include file. This is because the preprocessor My-Name value overrides the argument My-Name value, as shown:

```
&SCOPED-DEFINE My-Name "Donald"
MESSAGE "My-Name preprocessed in r-prprc3.i is" "{&My-Name} + "."
   VIEW-AS ALERT-BOX.
MESSAGE "My-Name argument in r-prprc3.i is" "{&My-Name}" + "."
   VIEW-AS ALERT-BOX.
```

Because the preprocessor My-Name defines a quoted "Donald" value, ABL replaces "{&My-Name}" in the fourth line with ""Donald"". This appears to the compiler as two empty strings and an unknown variable reference (Donald). Although you can do it with care, in general, avoid using the same names for compile-time arguments and preprocessor names.

Notes
- ABL expands preprocessor names wherever and in whatever context it finds them, including inside quoted character strings.
- If you define a preprocessor name in the same file and with the same name as a compile-time argument passed to the file, the value of the preprocessor name takes precedence over the value of the argument name from the point where the preprocessor name is defined.

See also
- &GLOBAL-DEFINE preprocessor directive, &SCOPED-DEFINE preprocessor directive, { } Argument reference, { } Include file reference, ; Special character

---

**&GLOBAL-DEFINE preprocessor directive**

Globally defines a compile-time constant (preprocessor name).

**Syntax**

```
&GLOBAL-DEFINE preprocessor-name definition
```

- `preprocessor-name`
  - The preprocessor name (compile-time constant) that you supply. ABL reserved keywords are allowed, but cannot be used in preprocessor expressions.

- `definition`
  - A string of characters (or preprocessor references that evaluate to a string of characters) whose content the preprocessor substitutes for `preprocessor-name` during compilation. If the definition is longer than one line, a tilde (\~) at the end of a line indicates continuation to the next line.

**Examples**

In this example, the preprocessor name MAX-EXPENSE is defined as the text string "5000":

```
&GLOBAL-DEFINE MAX-EXPENSE 5000
```
&IF, &THEN, &ELSEIF, &ELSE, and &ENDIF preprocessor directives

Wherever the reference \{&MAX-EXPENSE\} appears in the source code, the preprocessor substitutes the text string “5000”. For example, the preprocessor changes this line of code:

\[
&IF \text{ tot-amount} \leq \{&MAX-EXPENSE\} \text{ THEN DO:}
\]

To this line:

\[
&IF \text{ tot-amount} \leq 5000 \text{ THEN DO:}
\]

Notes

- You must place the &GLOBAL-DEFINE directive at the beginning of a line, preceded only by blanks, tab characters, or comments (/* comment */). The preprocessor trims all leading and trailing spaces from definition.

- The syntax of the &GLOBAL-DEFINE and &SCOPED-DEFINE directives are identical but these directives are used differently.

- If a duplicate &GLOBAL-DEFINE directive is used with out first

See also

{ } Preprocessor name reference, &SCOPED-DEFINE preprocessor directive, &UNDEFINE preprocessor directive, DEFINED preprocessor function

&IF, &THEN, &ELSEIF, &ELSE, and &ENDIF preprocessor directives

These directives set logical conditions for the inclusion of blocks of code to compile.

Syntax

\[
&IF \text{ expression} \&THEN \\
\text{ block} \\
[ &\&ELSEIF \text{ expression} \&THEN \\
\text{ block} ] \ldots \\
[ \&ELSE \\
\text{ block} ] \\
&\&ENDIF
\]

expression

An expression that can contain preprocessor name references, the operators listed in Table 6, the ABL functions listed in Table 7, and the DEFINED() preprocessor function.

When it encounters an &IF directive, the preprocessor evaluates the expression that immediately follows. This expression can continue for more than one line; the &THEN directive indicates the end of the expression. If the expression evaluates to TRUE, then the block of code between it and the next &ELSEIF, &ELSE, or &ENDIF is compiled. If the expression evaluates to FALSE, the block of code is not compiled and the preprocessor proceeds to the next &ELSEIF, &ELSE, or &ENDIF directive. No include files referenced in this block of code are included in the final source. You can nest &IF directives.
The expression that follows the &ELSEIF directive is evaluated only if the &IF expression tests false. If the &ELSEIF expression tests TRUE, the block of code between it and the next &ELSEIF, &ELSE, or &ENDIF directive is compiled. If the &ELSEIF expression tests FALSE, the preprocessor proceeds to the next &ELSEIF, &ELSE, or &ENDIF directive.

The block of code between the &ELSE and &ENDIF directives is compiled only if the &IF expression and the &ELSEIF expressions all test false. If there are no &ELSEIF directives, the block of code is compiled if the &IF expression tests false.

Once any &IF or &ELSEIF expression evaluates to TRUE, no other block of code within the &IF...&ENDIF block is compiled.

The &ENDIF directive indicates the end of the conditional tests and the end of the final block of code to compile.

Table 5 shows how preprocessor expressions are evaluated.

**Note**
When the preprocessor evaluates expressions, all arithmetic operations are performed with integers. Preprocessor name references used in arithmetic operations must evaluate to integers.

**See also**
&GLOBAL-DEFINE preprocessor directive, &SCOPED-DEFINE preprocessor directive, &UNDEFINE preprocessor directive
&MESSAGE preprocessor directive

Displays a message at compile time in the Compiler Messages dialog box.

Note: Does not apply to SpeedScript programming.

Syntax

```
&MESSAGE text-string
```

text-string

A string of characters, preprocessor name references, named include file arguments, or any combination of these that results in a character string to display. The `text-string` argument does not need to be quoted.

Examples

This is a possible compile-time message directive:

```
&MESSAGE Compiling the {&FILE-NAME} file.
```

If this fragment appears in a procedure file, `cmessage.p`, compiling this file with the COMPILE statement causes the following message to be included with the compiler messages:

```
Compiling the cmessage.p file.
```

See also

{ } Preprocessor name reference

&SCOPED-DEFINE preprocessor directive

Defines a compile-time constant (preprocessor name) non-globally.

Syntax

```
&SCOPED-DEFINE preprocessor-name definition
```

preprocessor-name

The preprocessor name (compile-time constant) that you supply. ABL reserved keywords are allowed, but cannot be used in preprocessor expressions.

definition

A string of characters (or preprocessor references that evaluate to a string of characters) whose content the preprocessor substitutes for `preprocessor-name` during compilation. If definition is longer than on line, a tilde (~) at the end of a line indicates continuation to the next line.
&UNDEFINE preprocessor directive

Notes

• You must place the &SCOPED-DEFINE directive at the beginning of a line, preceded only by blanks, tab characters, or comments (/* comment */). The preprocessor trims all leading and trailing spaces from definition.

• The syntax of the &GLOBAL-DEFINE and &SCOPED-DEFINE directives are identical but these directives are used differently.

See also

{ } Preprocessor name reference, &GLOBAL-DEFINE preprocessor directive, &UNDEFINE preprocessor directive, DEFINED preprocessor function

&UNDEFINE preprocessor directive

Undefines a compile-time constant (preprocessor name).

Syntax

```
&UNDEFINE preprocessor-name
```

preprocessor-name

The preprocessor name (compile-time constant) that you want to undefine.

Notes

• When you use the &UNDEFINE directive, ABL warns you if the name you want to undefine was not previously defined.

• The &UNDEFINE directive undefines the currently active name. It also undefines named include file arguments.

• To globally define the same name more than once, use this directive to undefine the name before redefining it. If you do not undefine the global name before redefining it, the compiler produces a warning message for non-globally (scoped) defined names. For globally defined names, &UNDEFINE is optional, but recommended for code readability. If &UNDEFINE is not used, the last &GLOBAL-DEFINE statement is used.

See also

&GLOBAL-DEFINE preprocessor directive, &SCOPED-DEFINE preprocessor directive, DEFINED preprocessor function

/* Comments */

Allows you to add explanatory text to a procedure between the /* and */ characters.

Syntax

```
/* comment */
```

commen

Descriptive text.

Note: Comments can be nested.
Examples

The r-comm.p example uses comments to document the history of procedure modifications.

```
/* Procedure written 9/5/87 by CHC
   revised 9/27/87 by DG */
FOR EACH Customer NO-LOCK:
END.
```

The r-comm2.p example uses comments to describe what the procedure does.

```
/* Step through unshipped orders */
FOR EACH Order NO-LOCK WHERE Order.ShipDate = ?:
   /* Display order date, promise date, terms */
   DISPLAY Order.OrderDate Order.PromiseDate Order.Terms.
   /*
   FOR EACH OrderLine OF Order NO-LOCK:
      /* Display all OrderLines of each Order */
      DISPLAY OrderLine.
   END.
   */
END.
```

The comment symbols that enclose the inner FOR EACH block turn that block into a comment for testing purposes. Since you can nest comments, ABL correctly processes any comments already in the bypassed code.

 Unary positive operator

Preserves the positive or negative value of a numeric expression. Do not confuse this operator with the addition operator that you use to add expressions together.

Syntax

```
+ expression
```

expression

An expression whose value is numeric.

Example

In the r-unpos.p example, the sign of CreditLimit is preserved as is the sign of the sum of CreditLimit + 100. The unary positive is not necessary; it is used simply to document the procedure, as shown:
### Addition operator

Adds two numeric expressions.

**Syntax**

```plaintext
expression + expression
```

**expression**

An expression whose value is numeric.

**Example**

In the following example, the addition operator (+) adds 100 to the value of the `CreditLimit` field:

```plaintext
r-addn.p
```

```plaintext
FOR EACH Customer:
    Customer.CreditLimit = Customer.CreditLimit + 100.
END.
```

**Note**

Adding two decimal expressions produces a DECIMAL value. Adding two INTEGER expressions produces an INTEGER value. Adding an integer expression (either INTEGER or INT64) and a decimal expression produces a DECIMAL value. Adding an INTEGER and an INT64 expression produces an INT64 value.

**See also**

– Subtraction operator

### Concatenation operator

Produces a character value by joining two character strings or expressions.

**Syntax**

```plaintext
expression + expression
```

**expression**

An expression whose value is a character string. If any expression is a LONGCHAR, the result is a LONGCHAR. Also, the result converts to the code page of the expression on the left.

---

The document text is as follows:

**r-unpos.p**

```
DEFINE VARIABLE old-max NO-UNDO LIKE CreditLimit LABEL "Old Limit".

FOR EACH Customer:
    old-max =+ Customer.CreditLimit.
    Customer.CreditLimit =+ (Customer.CreditLimit + 100).
    DISPLAY Customer.Name old-max Customer.CreditLimit.
END.
```

**See also**

– Unary negative operator
Example

The r-conc.p procedure prints mailing labels. It uses the concatenation operator (+) to ensure that the third line of each label shows the city and state separated by a comma and a space. The FORMAT x(16) is specified to provide room for up to 16 characters in the result of the concatenation. If a FORMAT is not given, then the AVM displays only the first eight characters of the result since x(8) is the default format for a character expression.

r-conc.p

```
FOR EACH Customer NO-LOCK:
    DISPLAY SKIP(1) Customer.Name SKIP Customer.Address SKIP
    Customer.PostalCode SKIP(2).
END.
```

This is a label produced by this procedure:

![Label example]

Note

If any of the string values you concatenate is the Unknown value (?), then the result is the Unknown value (?). This might lead to unexpected results if a field used in an expression is not mandatory. For example, you might have fields for a person’s first name, last name, and middle initial. You might combine these into a full name with an expression like the following:

```
DISPLAY fname + " " + minit + " " + lname FORMAT "x(36)".
```

If minit is not a mandatory field, it might be set to the Unknown value (?) in some records. If so, those records are displayed as the Unknown value (?). You can avoid this by using conditional code. For example:

```
DISPLAY fname + " " + (IF minit <> ? THEN minit + ". " ELSE "" ) + " " + 
    lname FORMAT "x(36)".
```

+ Date addition operator

Adds a number of days to a date, producing a date result.

Syntax

```
date + days
```

`date`

An expression that evaluates to a DATE value.
An expression with a value of the number of days you want to add to a date.

Example

The `r-dadd.p` procedure finds all unshipped orders that are at least one week overdue. If the order is not shipped and the promised date is more than seven days ago, the procedure finds the record for the customer who placed the order and displays the order and customer data.

```
r-dadd.p
DISPLAY "ORDERS SCHEDULED TO SHIP MORE THAN ONE WEEK LATE".
FOR EACH Order NO-LOCK WHERE Order.ShipDate = ?:
    IF TODAY > (Order.PromiseDate + 7) THEN DO:
        FIND Customer OF Order NO-LOCK.
        DISPLAY Order.OrderNum Order.CustNum Customer.Name Order.PromiseDate
        Customer.Terms.
    END.
END.
```

Notes

- To add a specific number of days and a specific number of milliseconds to a DATETIME, use the `DATETIME` function. For example:

  ```
  new-datetime = DATETIME( DATE(old-datetime) + days,
                             MTIME(old-datetime) + milliseconds ).
  ```

  The `DATETIME` function ensures that the time portion remains within the valid range, by adding day(s) to the date part when the time part goes over the number of milliseconds in a day.

- To add a specific number of days and milliseconds to a DATETIME-TZ, use the `DATETIME-TZ` function. For example:

  ```
  new-datetime-tz = DATETIME-TZ( DATE(old-datetime-tz) + days,
                                 MTIME (old-datetime-tz) + milliseconds,
                                 TIMEZONE(old-datetime-tz) ).
  ```

  The `DATETIME-TZ` function ensures that the time portion remains within the valid range, by adding day(s) to the date portion when the time part goes over the number of milliseconds in a day.

See also

- Date subtraction operator, + Datetime addition operator, ADD-INTERVAL function, DATE function

+ Datetime addition operator

Adds a number of milliseconds to a DATETIME or a DATETIME-TZ to produce another DATETIME or DATETIME-TZ.

Syntax

```
datetime + milliseconds
```
datetime-tz + milliseconds

datetime

An expression that evaluates to a DATETIME value.

milliseconds

An expression that evaluates to an integer value specifying a number of milliseconds.

datetime-tz

An expression that evaluates to a DATETIME-TZ value.

Example

This example returns the date and time exactly 24 hours later (dtTime) by calculating and adding the number of milliseconds in 24 hours to the present date and time (NOW function) and displays the result:

```sql
DEFINE VARIABLE dtTime AS DATETIME NO-UNDO.
DEFINE VARIABLE iHour AS INTEGER NO-UNDO INITIAL 3600000.
dtTime = NOW + (24 * iHour).
MESSAGE "A day later: " dtTime VIEW-AS ALERT-BOX.
```

Notes

- To add a specific number of days and a specific number of milliseconds to a DATETIME, use the DATETIME function. For example:

  ```sql
  new-datetime = DATETIME( DATE(old-datetime) + days,
                           MTIME(old-datetime) + milliseconds ).
  ```

  The DATETIME function ensures that the time portion remains within the valid range, by adding day(s) to the date part when the time part goes over the number of milliseconds in a day.

- To add a specific number of days and milliseconds to a DATETIME-TZ, use the DATETIME-TZ function. For example:

  ```sql
  new-datetime-tz = DATETIME-TZ( DATE(old-datetime-tz) + days,
                                MTIME(old-datetime-tz) + milliseconds,
                                TIMEZONE(old-datetime-tz) ).
  ```

  The DATETIME-TZ function ensures that the time portion remains within the valid range, by adding day(s) to the date portion when the time part goes over the number of milliseconds in a day.

See also

+ Date addition operator, – Datetime subtraction operator, ADD-INTERVAL function, DATETIME function, DATETIME-TZ function
– Unary negative operator

Reverses the sign of a numeric expression. Do not confuse this operator with the subtraction operator that subtracts one expression from another.

**Syntax**

```
- expression
```

**expression**

An expression whose value is numeric.

**Example**

If you supply a negative value for the variable `fx`, the `r-uneg.p` procedure uses the unary negative operator (-) to reverse the sign of `fx`, producing the absolute value of `fx` (`fabs-x`).

**r-uneg.p**

```pascal
DEFINE VARIABLE fx AS DECIMAL NO-UNDO LABEL "X".
DEFINE VARIABLE fabs-x AS DECIMAL NO-UNDO LABEL "ABS(X)".
REPEAT:
  SET fx.
  IF fx < 0 THEN
    fabs-x = -fx.
  ELSE
    fabs-x = fx.
  DISPLAY fabs-x.
END.
```

**See also**

+ Unary positive operator

– Subtraction operator

Subtracts one numeric expression from another numeric expression.

**Syntax**

```
expression - expression
```

**expression**

An expression with a numeric value.

**Example**

The `r-subt.p` procedure determines the amount of inventory available by subtracting the amount allocated from the total on hand.

**r-subt.p**

```pascal
DEFINE VARIABLE free-stock NO-UNDO LIKE on-hand LABEL "Free Stock".
FOR EACH Item NO-LOCK:
END.
```
Note
Subtracting one decimal expression from another produces a DECIMAL value. Subtracting one INTEGER expression from another produces an INTEGER. Subtracting an integer expression (INTEGER or INT64) from a decimal expression (or subtracting a decimal expression from an integer expression) produces a DECIMAL value. Subtracting a mix of INTEGER and INT64 expressions produces an INT64 value.

See also
+ Addition operator

-- Date subtraction operator

Subtracts a number of days from a date to produce a date result, or subtracts one date from another to produce an INTEGER result that represents the number of days between the two dates.

Syntax

date - { days | date }

date
An expression that evaluates to a DATE value.

days
An expression with a value of the number of days you want to subtract from date.

Example
This procedure finds all unshipped orders. If the promised date is more than one week ago, the procedure finds the customers who placed the order and displays the order and customer data.

r-dsub.p

DISPLAY "ORDERS SCHEDULED TO SHIP MORE THAN ONE WEEK LATE".
FOR EACH Order NO-LOCK WHERE Order.ShipDate = ?:
   IF (TODAY - 7) > Order.PromiseDate THEN
      DISPLAY Order.OrderNum Order.CustNum Order.PromiseDate
      (TODAY - Order.PromiseDate) LABEL "Days Late".
   END.

See also
+ Date addition operator, – Datetime subtraction operator, ADD-INTERVAL function, DATE function, INTERVAL function

-- Datetime subtraction operator

Subtracts a number of milliseconds from a DATETIME or a DATETIME-TZ to produce another DATETIME or DATETIME-TZ, or subtracts one DATETIME or DATETIME-TZ from another to produce an INT64 result in milliseconds.

Syntax

datetime - { milliseconds | datetime }

**datetime-tz**

An expression that evaluates to a DATETIME-TZ value.

---

**datetime**

An expression that evaluates to a DATETIME value.

**milliseconds**

An expression that evaluates to an integer value specifying a number of milliseconds.

**datetime-tz**

An expression that evaluates to a DATETIME-TZ value.

---

**Example**

This example returns the date and time exactly 24 hours ago (`dtTime`). It then recalculates the number of hours (`iHours`) from the number of milliseconds (`iMsec`) since then and displays the result:

```sql
DEFINE VARIABLE dtTime AS DATETIME NO-UNDO.
DEFINE VARIABLE iMsec AS INT64 NO-UNDO.
DEFINE VARIABLE iHour AS INTEGER NO-UNDO INITIAL 3600000.
DEFINE VARIABLE fHours AS DECIMAL NO-UNDO.

ASSIGN
  dtTime = NOW - (24 * iHour)
  iMsec = NOW - DATETIME-TZ(dtTime)
  fHours = iMsec / iHour.

MESSAGE "A day earlier: " dtTime "  "
  "Current hours since then: " fHours VIEW-AS ALERT-BOX.
```

---

**Notes**

- To get the number of days between two DATETIME or DATETIME-TZ variable values, use the **DATE function**. For example:

  ```sql
  num-days = DATE(dt2) - DATE(dt1)
  ```

  This operation does not take the time portion into account.

  To ensure the correct result when working with two DATETIME-TZ values, convert one of the values to the time zone of the other. For example:

  ```sql
  ASSIGN
    temp-dttz = dt1
    TIMEZONE(temp-dttz) = TIMEZONE(dt2)
    num-days = DATE(dt2) - DATE(temp-dttz).
  ```

- To subtract a specific number of days and milliseconds from a DATETIME, use the **DATETIME function**. For example:

  ```sql
  new-datetime = DATETIME( DATE(old-datetime) - days,
                            MTIME (old-datetime) - milliseconds ).
  ```
The DATETIME function ensures the time portion remains within a valid range by borrowing a day from the date portion, when necessary.

- To subtract a specific number of days and milliseconds from a DATETIME-TZ, use the DATETIME-TZ function. For example:

\[
\text{new-datetime-tz} = \text{DATETIME-TZ}( \text{DATE(old-datetime-tz)} - \text{days}, \\
\quad \text{MTIME(old-datetime-tz)} - \text{milliseconds}, \\
\quad \text{TIMEZONE(old-dateime-tz)} ).
\]

The DATETIME-TZ function ensures the time portion remains within a valid range by borrowing a day from the date portion, when necessary.

See also – Date subtraction operator, + Datetime addition operator, ADD-INTERVAL function, DATETIME function, DATETIME-TZ function, INTERVAL function

---

**Multiplication operator**

Multiplies two numeric expressions.

**Syntax**

\[
\text{expression} \times \text{expression}
\]

**expression**

An expression with a numeric value.

**Example**

This procedure computes the value of the on-hand inventory for each item. If the on-hand inventory is negative, the procedure sets the inventory value to 0.

**r-mult.p**

```sql
DEFINE VARIABLE inv-value AS DECIMAL NO-UNDO LABEL "VALUE".

FOR EACH Item NO-LOCK:
    IF inv-value < 0 THEN
        inv-value = 0.
    END.
END.
```

**Note**

Multiplying two decimal expressions produces a DECIMAL value. Multiplying two INTEGER expressions produces an INTEGER value. Multiplying two INT64 expressions produces an INT64 value. Multiplying an integer expression (INTEGER or INT64) and a decimal expression produces a DECIMAL value. Multiplying an INTEGER expression and an INT64 expression produces an INT64 value.

**See also** / Division operator
/ Division operator

Divides one numeric expression by another numeric expression, producing a decimal result. This is the case for both INTEGER and INT64 expressions.

**Syntax**

```
expression / expression
```

**expression**

An expression that evaluates to a numeric value.

**Example**

This procedure divides the number of items allocated by the number of items on hand, producing a decimal value. The multiplication operator (*) converts that decimal value to a percentage.

```
r-div.p
DISPLAY "INVENTORY COMMITMENTS AS A PERCENT OF UNITS ON HAND".
FOR EACH Item NO-LOCK:
    DISPLAY Item.ItemNum Item.ItemName Item.Allocated Item.OnHand
        (Item.Allocated / Item.OnHand) * 100 FORMAT ">>9" LABEL "PCT".
END.
```

**Notes**

- ABL always performs division as a decimal operation (the product of 5 / 2 is 2.5, not 2). If you assign the result to an integer field, ABL rounds the decimal to make the assignment. When you want ABL to truncate a quotient to an integer, use the TRUNCATE function (TRUNCATE(5 / 2, 0) is 2).
- The result of dividing a number by 0 is the Unknown value (?), and the AVM does not display an error message.

**See also**

* Multiplication operator

---

**ABSOLUTE function**

Returns the absolute value of a numeric value.

**Syntax**

```
ABSOLUTE ( n )
```

**n**

An integer or decimal expression. The return value is the same format as n.

**Example**

This procedure calculates the number of miles you drive between highway exit ramps.
ACCUM function

Returns the value of an aggregate expression that is calculated by an ACCUMULATE or aggregate phrase of a DISPLAY statement.

Syntax

\[
\text{ACCUM aggregate-
phrase expression}
\]

aggregate-phrase

A phrase that identifies the aggregate value it should return. This is the syntax for aggregate-phrase:

Syntax

\[
\{ \text{AVERAGE} | \text{COUNT} | \text{MAXIMUM} | \text{MINIMUM} | \text{TOTAL} | \text{SUB-AVERAGE} | \text{SUB-COUNT} \\
| \text{SUB-MAXIMUM} | \text{SUB-MINIMUM} | \text{SUB-TOTAL} \} [ \text{BY break-group} ]
\]

For more information on aggregate items, see the Aggregate phrase reference entry.

expression

An expression that was used in an earlier ACCUMULATE or DISPLAY statement. The expression you use in the ACCUMULATE or DISPLAY statement and the expression you use in the ACCUM function must be in exactly the same form. (For example, “on-hand * cost” and “cost * on-hand” are not in exactly the same form.) For the AVERAGE, SUB-AVERAGE, TOTAL, and SUB-TOTAL aggregate phrases, expression must be numeric.

Example

This procedure shows a total for the extended price of each item on an order. The running total of the order is displayed as well as the order total and grand total for all orders. This procedure accumulates totals at three levels.
ACCUMULATE statement

Calculates one or more aggregate values of an expression during the iterations of a block. Use the ACCUM function to access the result of this accumulation.

Syntax

```
ACCUMULATE { expression ( aggregate-phrase ) } ... 
```

expression

An expression for which you want to calculate the aggregate value. The expression you use in the ACCUMULATE statement and the expression you use in the ACCUM function (when using the result of the ACCUMULATE statement) must be in exactly the same form. (For example, “A * B” and “B * A” are not in exactly the same form.)

aggregate-phrase

Identifies one or more values to calculate based on a change in expression or a break group. This is the syntax for aggregate-phrase:

Syntax

```
{ AVERAGE | COUNT | MAXIMUM | MINIMUM | TOTAL | SUB-AVERAGE 
  | SUB-COUNT | SUB-MAXIMUM | SUB-MINIMUM | SUB-TOTAL 
} ... [ BY break-group ] ... 
```

For more information, see the Aggregate phrase reference entry.

Examples

This procedure calculates and displays statistics for all customers, but does not show the detail for each customer.
The following procedure lists each item with its inventory value and lists that value as a percentage of the total inventory value of all items; it sorts items by highest value.

**r-acmlt.p**

FOR EACH Customer NO-LOCK:
  ACCUMULATE Customer.CreditLimit (AVERAGE COUNT MAXIMUM).
END.

DISPLAY "MAX-CREDIT STATISTICS FOR ALL CUSTOMERS:" SKIP(2)
  "AVERAGE =" (ACCUM AVERAGE Customer.CreditLimit) SKIP(1)
  "MAXIMUM =" (ACCUM MAXIMUM Customer.CreditLimit) SKIP(1)
  "NUMBER OF CUSTOMERS =" (ACCUM COUNT Customer.CreditLimit) SKIP(1)
WITH NO-LABELS.

The following procedure displays all customers, sorted by salesrep and country within the list for each salesrep. The procedure calculates the balance for each customer, total balance for each country, and total balance for each salesrep.

**r-acmlt2.p**

FOR EACH Item NO-LOCK:
END.

FOR EACH Item NO-LOCK BY Item.OnHand * Item.Price DESCENDING:
END.

The following procedure lists each item with its inventory value and lists that value as a percentage of the total inventory value of all items; it sorts items by highest value.

**r-ac.p**

FOR EACH Customer NO-LOCK BREAK BY Customer.SalesRep BY Customer.Country:
  ACCUMULATE Customer.Balance
IF LAST-OF(Customer.Country) THEN
  COLUMN-LABEL "Country!Total".
IF LAST-OF(Customer.SalesRep) THEN DO:
  DISPLAY Customer.SalesRep ACCUM TOTAL BY Customer.SalesRep
  Customer.Balance COLUMN-LABEL "SalesRep!Total".
  DOWN 1.
END.
END.

**Note**

You can use the ACCUMULATE statement only in blocks with the implicit looping property. ABL automatically supplies looping services to REPEAT and FOR EACH blocks. See *OpenEdge Getting Started: ABL Essentials* for more information on block properties.

**See also**

ACCUM function, Aggregate phrase
ACTIVE-FORM system reference

(Windows only; GUI for .NET only)

An object reference to the last .NET form or ABL window to receive focus. The object reference returned by ACTIVE-FORM has the OpenEdge .NET Progress.Windows.IForm interface type.

Syntax

ACTIVE-FORM

Notes

• ACTIVE-FORM references instances of any class that ABL recognizes as a form, including the following form classes:

  – Progress.Windows.Form class — A custom OpenEdge .NET form class that encapsulates a Microsoft .NET System.Windows.Forms.Form for use within an ABL session. If a .NET form is last to receive focus and you use the Progress.Windows.Form class to instantiate all .NET forms, ACTIVE-FORM references the affected Progress.Windows.Form instance.

  – Progress.Windows.FormProxy class — An OpenEdge .NET form class that is associated with each ABL window instantiated in any ABL session that references .NET objects. If an ABL window is last to receive focus, ACTIVE-FORM references the Progress.Windows.FormProxy object associated with the affected window.

• If the last ABL window to receive focus is the default window, ACTIVE-FORM returns the Unknown value (?), because ABL does not create a FormProxy object for the default window.

• You cannot use ACTIVE-FORM if the window with focus is not a Progress.Windows.Form or a native ABL window. If you directly instantiate .NET forms using System.Windows.Forms.Form (or any other native .NET form class), you must use the .NET ActiveForm property to identify the native .NET form instance that has focus. Progress.Windows.Form also inherits the ActiveForm property from System.Windows.Forms.Form, and this property also references the .NET native form instance that a given Progress.Windows.Form object represents. However, Progress.Windows.FormProxy does not inherit the ActiveForm property and does not provide a meaningful reference when an ABL window has focus.

See also

ACTIVE-WINDOW system handle, Progress.Windows.Form class, Progress.Windows.FormProxy class

ADD-INTERVAL function

Adds a time interval to, or subtracts a time interval from, a DATE, DATETIME, or DATETIME-TZ value, and returns the new value.

Syntax

ADD-INTERVAL (datetime, interval-amount, interval-unit)

datetime

An expression whose value is a DATE, DATETIME, or DATETIME-TZ.
interval-amount

A signed integer (positive or negative) indicating the amount of time you want to add to
or subtract from datetime value.

interval-unit

A character constant, or a character expression that evaluates to one of the following time
These values are case insensitive and may be singular.

Note

To add or subtract months or years, this function converts the date to Gregorian before adding
or subtracting the year or month value. If the result is an invalid date, the function decrements
the day part of the date until a valid date is obtained. For example:

• Adding 1 month to January 30, 2003 yields February 28, 2003

• Adding 13 months to January 30, 2003 yields February 29, 2004 (2004 is a leap year)

• Subtracting 1 month from December 31, 2003 yields November 30, 2003

subtraction operator, DATE function, DATETIME function, DATETIME-TZ function,
INTERVAL function

Aggregate phrase

Identifies one or more values to calculate based on a change in an expression or a break group.

Syntax

```
{   AVERAGE
    | COUNT
    | MAXIMUM
    | MINIMUM
    | TOTAL
    | SUB-AVERAGE
    | SUB-COUNT
    | SUB-MAXIMUM
    | SUB-MINIMUM
    | SUB-TOTAL
} ... [ LABEL aggr-label ] [ BY break-group ] ...
```

AVERAGE

Calculates the average of all of the values of the expression in a break group and the
average of all of the values of the expression in all break groups.

COUNT

Calculates the number of times the expression was counted in a break group and the count
of all the values in all break groups.
MAXIMUM

Calculates the maximum of all of the values of the expression in a break group and the maximum of all the values of the expression in all break groups.

MINIMUM

Calculates the minimum of all of the values of the expression in a break group and the minimum of all the values of the expression in all break groups.

TOTAL

Calculates the subtotal of all of the values of the expression in a break group and the grand total of all of the values of the expression in all break groups. When you use default aggregates, the actual display of the grand total is deferred until the frame goes out of scope.

SUB-AVERAGE

Averages values in a break group. Does not supply an average for all records, just for those in each break group.

SUB-COUNT

Counts the number of times an expression is in a break group. Does not supply a count for all records, just for those in each break group.

SUB-MAXIMUM

Shows the maximum value of an expression in a break group. Does not supply a maximum value for all records, just for those in each break group.

SUB-MINIMUM

Shows the minimum value of an expression in a break group. Does not supply a minimum value for all records, just for those in each break group.

SUB-TOTAL

Subtotal all of the values of the expression in a break group. Does not supply a total value for all records, just for those in each break group.

BY break-group

Performs aggregation for break groups if you use the BREAK option in a FOR EACH block header.

LABEL  aggr-label

Specifies a label for the aggregate value. aggr-label is a standard ABL string and can use a string attribute. The string can be translated by Translation Manager II. You can specify a maximum length attribute that is greater than the length of the longest label translation.

Examples

This procedure lists the customer information for all customers (categorized by country) and a subtotal of each country’s balance. If you use TOTAL instead of SUB-TOTAL, the AVM displays a grand total.
In the following procedure, the AVM displays the result of the COUNT aggregate even though no accumulation has occurred. In this example, COUNT displays as 0.

In the following procedure, the AVM uses “Avg. Credit Limit” and “Max. Credit Limit” as the labels for the AVERAGE and MAXIMUM aggregates respectively.

**Notes**

- By default, the AVM displays the aggregate result when the aggregate group ends, as long as the block iterates. If you want to suppress automatic display of zero aggregates, use the ACCUMULATE statement to perform the calculation and test the result with the ACCUM function before displaying the result.

- When you use aggregate phrases to accumulate values within shared frames, you must include the ACCUM option in the Frame phrase. See the Frame phrase reference entry for more information.

- An Aggregate phrase is designed to generate aggregate values for blocks that read forward through records in a sequential fashion. In blocks that read records in a non-sequential fashion (for example, FIND PREV, FIND FIRST, FIND LAST, etc.), an aggregate could yield unexpected values.

- Avoid specifying more than one aggregate of the same type for a single field in a block. If an aggregate of the same type for a single field executes more than once during a single iteration of a block, the aggregate could yield unexpected value.

- The BY phrase supports aggregates on break groups. The aggregate for a break group should reside in the block that defines the break group. Avoid positioning the aggregate in a conditional statement or sub-block in the block that defines the break group. Failure to follow these guidelines may yield unexpected values for the aggregate.

You can build your own algorithms to generate aggregates for break groups in situations that do not adhere to these guidelines. For example, you can use variables to store...
aggregate values for use in expressions that generate the appropriate aggregate values for
break groups across blocks in a procedure.

See also ACCUMULATE statement, FOR statement
**ALIAS function**

The ALIAS function returns the alias corresponding to the integer value of expression.

**Syntax**

```
ALIAS ( integer-expression )
```

**integer-expression**

If there are, for example, three currently defined aliases, the functions ALIAS(1), ALIAS(2), and ALIAS(3) return them. If the ALIAS function cannot find a defined alias, it returns the Unknown value (?). For example, building on the previous example of three defined aliases, the functions ALIAS(4), ALIAS(5), and ALIAS(6) return the Unknown value (?) because they cannot find a defined alias.

**Example**

This procedure displays the aliases and logical names of all connected databases.

```
r-aliasf.p
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
REPEAT ix = 1 TO NUM-ALIASES:
    DISPLAY ALIAS(ix) LABEL "Alias"
    LDBNAME(ALIAS(ix)) LABEL "Logical Database".
END.
```

**See also**

CONNECT statement, CONNECTED function, CREATE ALIAS statement, CREATE CALL statement, DATASERVERS function, DBCODEPAGE function, DBCOLLATION function, DBRESTRICTIONS function, DBTYPE function, DBVERSION function, DELETE ALIAS statement, DISCONNECT statement, FRAME-DB function, LDBNAME function, NUM-ALIASES function, NUM-DBS function, PDBNAME function, SDBNAME function

---

**AMBIGUOUS function**

Returns a TRUE value if the last FIND statement for a particular record found more than one record that met the specified index criteria.

**Syntax**

```
AMBIGUOUS record
```

**record**

The name of a record or record buffer used in a previous FIND statement.

To access a record in a table defined for multiple databases, you might have to qualify the record’s table name with the database name. See the Record phrase reference entry for more information.
AND operator

Example

The following example retrieves a customer record based on a name (cname) supplied by the user. If the procedure finds a record, it displays fields from that record. If it does not find a record because more than one record matched the selection criteria (name = cname), it displays the message: “There is more than one customer with that name.” If it does not find a record because no records matched the selection criteria, it displays “Cannot find customer with that name”.

r-ambig.p

```sql
DEFINE VARIABLE cName NO-UNDO LIKE Customer.Name LABEL "Cust Name".
REPEAT:
  SET cName.
  FIND Customer NO-LOCK WHERE Customer.Name = cName NO-ERROR.
  IF AVAILABLE Customer THEN
    Customer.PostalCode.
  ELSE IF AMBIGUOUS Customer THEN
    MESSAGE "There is more than one customer with that name".
  ELSE
    MESSAGE "Cannot find customer with that name".
  END.
FIND Customer WHERE Customer.Name BEGINS "".
FIND Employee WHERE Employee.LastName = "Smith"
AND Employee.FirstName BEGINS "".
```

Sometimes the AMBIGUOUS function returns a TRUE value when there is no ambiguity. For example, if there is exactly one customer record, the following statement finds that record. Otherwise, the following statement always returns a message of “not found” rather than “ambiguous”:

```sql
FIND Customer WHERE Customer.Name BEGINS "".
```

Additionally, the following statement succeeds if there is only one Smith listed in the database:

```sql
FIND Employee WHERE Employee.LastName = "Smith"
AND Employee.FirstName BEGINS "".
```

Note

AMBIGUOUS is useful only when there is an index. If you use the AMBIGUOUS function to test a work file record, the function returns a value of FALSE because work files do not have indexes.

See also

AVAILABLE function, FIND statement, LOCKED function, NEW function (record buffers)

AND operator

Returns a TRUE value if each logical expression is TRUE.

Syntax

```
expression AND expression
```

expression

An expression that evaluates to a logical value (TRUE or FALSE).
Example

This procedure lists all customers with credit limits between two values (supplied by the user and stored in the variables low-credit and hi-credit). The expressions Customer.CreditLimit >= low-credit and Customer.CreditLimit <= hi-credit are logical expressions because each yields a true or false value. Using the AND operator to join these logical expressions results in a logical expression that follows the WHERE keyword.

```
DEFINE VARIABLE low-credit LIKE credit-limit LABEL "Low Credit Limit".
DEFINE VARIABLE hi-credit LIKE credit-limit LABEL "High Credit Limit".
REPEAT:
  SET low-credit hi-credit WITH FRAME cr-range.
  FOR EACH Customer NO-LOCK WHERE
    (Customer.CreditLimit >= low-credit) AND
    (Customer.CreditLimit <= hi-credit):
  END.
END.
```

See also
NOT operator, OR operator

**APPLY statement**

Applies an event to a widget or procedure.

**Syntax**

```
APPLY event [ TO widget-phrase ]
```

**event**

An expression whose value is the key code or event name that you want to apply. A special value of event is the value of the LASTKEY function. The LASTKEY function returns the keycode for the last event read from the user (that is, from the keyboard or mouse) or the last character read from an input file. The value event can be either a character-string value (event name) or an integer (key code) expression. For more information on default system actions and events, see the “Handle-based Object Events Reference” section on page 1827.

**TO widget-phrase**

Specifies a widget or procedure to which the event is applied.

**Example**

This procedure shows how to use the APPLY statement to create keyboard accelerators. When you run this procedure you can invoke the trigger block attached to the order-but button by choosing the button directly or by pressing F10 in the Name field. When you press F10, the AVM sends the CHOOSE event to the button. This is equivalent to choosing the button with the mouse.
### Notes

- You can apply any event to any widget, including an insensitive widget. Most event-widget pairs have a default system action, but a few do. For example, the default system action for the A event on a fill-in widget is to insert the letter A into the fill-in at the current cursor location; however, there is no default system action for the A event on a button widget. Also, if you APPLY an event to a button, for example, the image of the button does not “depress” and then “pop back out.” Depending on the event-widget pair, the APPLY statement may or may not perform the default system action.

Regardless of whether there is a default system action associated with an event-widget pair, you can write a trigger for the pair. The APPLY statement executes a trigger associated with an event-widget pair. If the event-widget pair has a default system action, that action occurs before or after the trigger executes, depending on the event. For more information on default system actions and events, see the next note and the “Handle-based Object Events Reference” section on page 1827.

- When, in a graphical interface, you APPLY an event to a widget, you cannot easily invoke the widget animation code that runs when the user interacts with the widget physically. For example, if you APPLY a “choose” event to a button widget, you cannot easily make the image of the button move down and up, as occurs when the user clicks on the button. The difficulty exists because the AVM does not provide access to the widget animation code, which resides in the windowing system. When the user clicks on the button, the windowing system detects the event, invokes the button animation code, perhaps performs other tasks, and passes the event to the AVM, which invokes the trigger code associated with the event. When you APPLY a “choose” event to the button, the AVM merely invokes the trigger code associated with the event. In neither case does the AVM access, or provide access to, the button animation code.

One widget that does not have this difficulty is the fill-in. When you APPLY a character-string event to a fill-in, the character string appears in the image of the fill-in. The AVM accomplishes this by placing a copy of the character string into a buffer that maps to the same portion of the screen as the image of the fill-in.

- The APPLY statement serves as an important communications mechanism between procedures in an application. By defining triggers for events in a procedure, you can...
encapsulate functionality in the procedure. The APPLY statement allows you to access that encapsulated functionality from another procedure through a simple event interface.

- The APPLY statement is double-byte enabled. A character-string value specified for the event argument can contain double-byte characters.

- If a procedure calls another procedure from within an EDITING phrase and the called procedure uses the APPLY statement, the effect is the same as if the APPLY statement occurred directly within the EDITING phrase.

- If you are using APPLY in an EDITING phrase and expression is a key that causes a GO action (GO, or any key in a list used with the GO-ON option), the AVM does not immediately exit the EDITING phrase but instead processes all the remaining statements in the phrase. If RETRY, NEXT, UNDO RETRY, or UNDO NEXT is executed before the end of the phrase, the AVM ignores the GO and continues processing the EDITING phrase.

- APPLY -2 is the same as APPLY ENDKEY.

- For SpeedScript, you can apply an event to a procedure only.

- You cannot use the APPLY statement to apply (publish or send) an event on behalf of a .NET object. .NET provides its own mechanisms for publishing events. In some cases, this might include a method for publishing a given event on behalf of the object. For more information, see the .NET development documentation on MSDN.

See also ON statement, Widget phrase

---

ASC function

Converts a character expression representing a single character into the corresponding ASCII (or internal code page) value, returned as an INTEGER.

Syntax

```
ASC ( expression [, target-codepage [, source-codepage ] ] )
```

**expression**

An expression with a value of a single character that you want to convert to an ASCII (or internal code page) integer value. If expression is a constant, you must enclose it in quotation marks (" "). If the value of expression is other than a single character, ASC returns the value -1.

The values for expression are case sensitive. For example, ASC("a") returns a different value than ASC("A").

**target-codepage**

A character-string expression that evaluates to the name of a code page. The name that you specify must be a valid code page name available in the OpenEdge-instal1-dir/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management). If you supply a non-valid name, the ASC function
returns the value -1 and returns a runtime error. Before returning an integer value, the ASC function converts expression from source-codepage to target-codepage. The returned integer value is relative to target-codepage. If you do not specify target-codepage, the value returned is the code page identified with the Internal Code Page (-cpinternal) parameter.

**source-codepage**

A character-string expression that evaluates to the name of a code page. The name that you specify must be a valid code page name available in the OpenEdge-install-dir/convmap.cp file. If you supply a non-valid name, the ASC function returns the value -1. The source-codepage specifies the name of the code page to which expression is relative. The default value of source-codepage is the code page identified with the Internal Code Page (-cpinternal) parameter.

**Example**

The following procedure counts how many customers names begin with each of the letters, A-Z. It counts all other customers separately. The procedure uses the ASC function to translate a letter into an integer that it uses as an array subscript for counting.

**r-asc.p**

```plaintext
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE jx AS INTEGER NO-UNDO.
DEFINE VARIABLE ltrl AS INTEGER NO-UNDO EXTENT 27.

FOR EACH Customer NO-LOCK:
    ix = ASC(SUBSTRING(Customer.Name,1,1)).
    IF ix < ASC("A") or ix > ASC("Z") THEN ix = EXTENT(ltrl).
    ELSE ix = ix - ASC("A") + 1.
END.

DO jx = 1 TO EXTENT(ltrl) WITH NO-LABELS USE-TEXT:
    IF jx <= 26 THEN
        DISPLAY CHR(ASC("A") + jx - 1) @ ltr-name AS CHARACTER FORMAT "x(5)".
    ELSE
        DISPLAY "Other" @ ltr-name.
    DISPLAY ltrl[jx].
END.
```

**Notes**

- The ASC function returns the corresponding value in the specified character set. By default, the value of SESSION:CHARSET is iso8859-1. You can set a different internal code page by specifying the Internal Code Page (-cpinternal) parameter. For more information, see *OpenEdge Development: Internationalizing Applications*.

- The ASC function is double-byte enabled. If the expression argument yields a double-byte character, this function returns a value greater than 255 and less than 65535.

**See also**

CHR function, CODEPAGE-CONVERT function, INTEGER function, SESSION system handle

---

**Assignment (=) statement**

Assigns the value of an expression to a database field or variable.
Data movement

![Diagram showing data movement from database to field or variable, then to expression and screen buffer]

Syntax

\[ \text{field} = \text{expression} \ [\ NO-ERROR \ ] \]

\textit{field}

The name of an ABL data element to which you want to assign the value of \textit{expression} and that is defined with a data type that is compatible with the data type of \textit{expression}. This data element can include a:

- Database or temp-table field
- Variable scoped to the current procedure, user-defined function, or method of a class or an accessible class-based variable data member, including a subscripted or unsubscripted array variable
- Parameter defined for the current procedure, user-defined function, or method of a class, including a subscripted or unsubscripted array parameter
- Writable class-based or COM property, including a subscripted or unsubscripted array property
- Writable handle attribute (such as PRIVATE-DATA)
- Writable system handle (such as CURRENT-WINDOW)
- ABL syntax that specifies a keyword-driven assignment statement (such as the PROPATH statement, SUBSTRING statement, or similar statement)

\textit{expression}

An expression with a data type that is consistent with the data type of \textit{field}. For more information, see the Expression reference entry.

\textit{NO-ERROR}

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the \texttt{ERROR-STATUS} system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

For the Assignment (=) statement with \textit{NO-ERROR}, if \texttt{ERROR} is raised, then the leftside of the assignment will be unchanged.
To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE(message-num) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Example**

This procedure resets all the monthly quota values to 2500 in all salesrep records. If you want to set values for individual array elements, you can do so by making an explicit assignment using the assignment statement and a specific array reference, such as month-quota[1] or month-quota[i].
Notes

- If `field` is an integer and `expression` is a decimal, the AVM rounds the value of the expression before assigning it. If `field` is a decimal and `expression` is a decimal, the AVM rounds the value of the expression to the number of decimal places defined for the field in the Data Dictionary, or defined or implied for a variable or temp-table field.

- If `field` is an ABL array type (defined with EXTENT) and `expression` is not an array, and you do not identify a particular array element, the AVM stores `expression` in each element of the array. If you identify a particular element, the AVM stores `expression` in the specified array element.

- If both `field` and `expression` are ABL array types, the AVM copies the data for all `expression` array elements into the corresponding elements of the `field` array. This is known as a deep copy.

- An indeterminate array is one where the size of the EXTENT is not yet fixed. A determinate array is one where the EXTENT size is fixed. When deep copying one array to another, the following rules apply:
  - If both the array on the left-hand side and the right-hand side of the equation are determinate arrays, the EXTENT size must match or the AVM raises an error.
  - You cannot assign an indeterminate array to a determinate array.
  - You can assign any array to an indeterminate array, but you cannot assign a scalar value to an indeterminate array.

- ABL allows you to assign ABL arrays and .NET array objects to each other. How an array assignment works between ABL and .NET arrays depends upon the array type of `field` (the target of the assignment) and the array type of `expression` (the source for the assignment). For more information, see the Data types reference entry.

- If `expression` is an ABL handle-based object (for example, a temp-table, ProDataSet, widget, or socket), `field` must be a temp-table field, variable, or other ABL data element defined as a compatible handle. In this case, the AVM assigns only the handle of the ABL handle-based object to `field`, not the entire object and its contents.

- If you assign a value to a database field, any ASSIGN trigger associated with that field executes at the end of the assignment statement (after any index changes are made). If the trigger raises ERROR, the assignment fails and the database changes are undone.

- You can embed an assignment in a SET or UPDATE statement.

- For multiple assignments, use the ASSIGN statement. This is more efficient than multiple assignment statements.
Assignment (=) statement

- If field is a handle, the expression on the right-hand-side must also evaluate to a handle value that is specified using an appropriate reference to a handle-based object handle. For more information on object handle references, see the “Handle Attributes and Methods Reference” section on page 1271.

- You can assign DATE, DATETIME, and DATETIME-TZ data. When the data type expression on the left side of the assignment statement contains more information than the data type expression on the right side provides (for example, datetime-tz = date where a DATETIME-TZ value contains more information than a DATE value), the time value defaults to midnight and the time zone value defaults to the session’s time zone. When the data type expression on the left side of the assignment statement contains less information than the data type expression on the right side provides (for example, date = datetime-tz where a DATE value contains less information than a DATETIME-TZ value), the AVM converts the DATETIME-TZ value to the local date and time of the session, then drops the time and time zone.

- Starting with Version 9.1, you can assign RAW values to MEMPTR variables and MEMPTR values to RAW variables. If the target variable is a RAW data type, the AVM re-sizes the target variable, if necessary, so that after the assignment is the same size as the source. Note that after the assignment (whether RAW = MEMPTR or MEMPTR = RAW), the target variable has a copy of the memory associated with the source—each variable has an independent copy of the data.

- You can assign large object data from one BLOB or MEMPTR to another, and from one CLOB, LONGCHAR, or CHARACTER to another. You cannot assign large object data between BLOBs and CLOBs or MEMPTRs and LONGCHARs. You can accomplish this, indirectly, by using the COPY-LOB statement. For more information, see the COPY-LOB statement reference entry.

Note: When assigning BLOB or CLOB fields, the field must appear by itself on either the right-hand or the left-hand side of the assignment.

Table 8 lists the default character conversions that the AVM performs when assigning CLOB, LONGCHAR, and CHARACTER data between a source and target object. References to CLOBCP and CLOBDB represent CLOB data in either the CLOB’s defined code page or the database’s defined code page, respectively. References to the “fixed code page” represent the code page of a target LONGCHAR variable set using the FIX-CODEPAGE statement.

Table 8: Default assignment character conversions

<table>
<thead>
<tr>
<th>When the target object (on the left) is a . . .</th>
<th>And the source object (on the right) is a . . .</th>
<th>The AVM converts the data in the source object to . . .</th>

</tbody>
</table>
• When you assign the Unknown value (?) to a BLOB or CLOB field, the AVM deletes any associated object data.

• If \textit{expression} is a solitary invocation of the \textit{NEW function (classes)}, this statement represents and conforms to the rules specified for the NEW statement.

• If \textit{expression} evaluates to an object reference value, \textit{field} must also be a data element defined as a class or interface type that is type-compatible with \textit{expression} according to the rules for assigning references to class instances defined for the NEW statement. For more information, see the NEW statement reference entry. Thus, you can assign one object reference variable to another object reference variable when the destination object reference (on the left side of the assignment) is defined for the same class, a super class, or an interface of the object reference being assigned (on the right side of the assignment). The destination object reference retains its defined class or interface type for compilation. However, following its assignment, at run time, the destination represents the subclass of \textit{field} (or the class that implements the interface specified by \textit{field}) that is defined by \textit{expression}.

If \textit{field} has a class type that is a subclass lower in the class hierarchy than the class type represented by \textit{expression}, you can cast \textit{expression} to the type of \textit{field} using the CAST function, but only if \textit{expression} is a super class that actually contains an instance of the \textit{field} class type. If \textit{field} has a class type that implements an interface type represented by \textit{expression}, you can similarly cast \textit{expression} using the CAST function, but only if \textit{expression} actually contains an instance of the \textit{field} class type. For more information about the CAST function, see the CAST function reference entry.

After the assignment, \textit{field} contains a copy of the object reference value returned by \textit{expression}, which points to the same object instance, not a copy of the object referenced by \textit{expression}.

• Although you can assign an object reference to a temp-table field defined as a \textit{Progress.Lang.Object class} type, you cannot assign an object reference to a field in a
ASSIGN statement

Moves data previously placed in the screen buffer by a data input statement or moves data specified within the ASSIGN statement by an expression to the corresponding fields and variables in the record buffer.

Syntax

```
ASSIGN {
    [ INPUT ] FRAME frame | BROWSE browse ]
    { field [ = expression ] } [ WHEN expression ]
} ... [ NO-ERROR ]

ASSIGN { record [ EXCEPT field ... ] } [ NO-ERROR ]
```

**field**

The name of the field or variable to be set from the corresponding value found in the screen buffer or expression. The field must be qualified by a frame name (frame) or browse name (browse) if field is specified as an input widget in more than one frame. If field is set from expression, field can include all of the elements that are defined for the left side of an Assignment (=) statement.

**expression**

An expression with a data type that is consistent with the data type of field. In this case, the AVM determines the field value from the expression rather than from the screen buffer. For more information on expression, see the Expression reference entry.

**WHEN expression**

Moves data to the record buffer only when expression has a value of TRUE. Here, expression is a field name, variable name, or expression whose value is logical. The AVM evaluates WHEN expressions at the beginning of the assignment, before any assignments take place.
NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

For the ASSIGN statement with NO-ERROR, if an ERROR condition is raised, every instance of field remains unchanged.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE(message-num) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the
ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**record**

The record buffer name with the fields set, from the corresponding values in the screen buffer. Naming a record is a shorthand way to list each field in that record individually.

To use ASSIGN with a record in a table defined for multiple databases, you might have to qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

**EXCEPT field**

All fields in the record buffer are affected except for those listed. Separate field names with a space.

**Examples**

The following procedure prompts you for a customer number and retrieves the customer record if one exists, or creates a new one if it does not exist. If it creates a new record, the value for the CustNum field is ASSIGNED from the value you entered in response to the PROMPT-FOR statement.

```plaintext
r-asgn.p

REPEAT:
  PROMPT-FOR Customer.CustNum.
  FIND Customer USING Customer.CustNum NO-ERROR.
  IF NOT AVAILABLE Customer THEN DO:
    CREATE Customer.
    ASSIGN Customer.CustNum.
  END.
  UPDATE Customer WITH 2 COLUMNS.
END.
```

The next procedure changes the order number and line number of an order-line record. (It copies an order-line from one order to another.) It sets the new values into variables and modifies the record with a single ASSIGN statement that contains two assignment phrases in the form field = expression. Thus, both fields are changed within a single statement. Because the AVM re-indexes records at the end of any statement that changes an index field value, and because OrderLine.OrderNum and OrderLine.LineNum are used jointly in one index, this technique does not generate an index until both values change.

```plaintext
r-asgn2.p

DEFINE VARIABLE neword LIKE order-line.order-num LABEL "New Order".
DEFINE VARIABLE newordli LIKE order-line.line-num LABEL "New Order Line".

REPEAT:
  SET neword newordli.
  FIND Order WHERE Order.OrderNum = neword.
  ASSIGN
    OrderLine.OrderNum = neword
    OrderLine.LineNum = newordli.
END.
```
Notes

- If field is an integer and expression is a decimal, the AVM rounds the value of the expression before assigning it. If field is a decimal and expression is a decimal, the AVM rounds the value of the expression to the number of decimal places defined for the field in the Data Dictionary, or defined or implied for a variable or temp-table field.

- If field is an ABL array type (defined with EXTENT) and expression is not an array, and you do not identify a particular array element, the AVM stores expression in each element of the array. If you identify a particular element, the AVM stores expression in the specified array element.

- If both field and expression are ABL array types, the AVM copies the data for all expression array elements into the corresponding elements of the field array. This is known as a deep copy.

- An indeterminate array is one where the size of the EXTENT is not yet fixed. A determinate array is one where the EXTENT size is fixed. When deep copying one array to another, the following rules apply:
  - If both the array on the left-hand side and the right-hand side of the equation are determinate arrays, the EXTENT size must match or the AVM raises an error.
  - You cannot assign an indeterminate array to a determinate array.
  - You can assign any array to an indeterminate array, but you cannot assign a scalar value to an indeterminate array.

- ABL allows you to assign ABL arrays and .NET array objects to each other. How an array assignment works between ABL and .NET arrays depends upon the array type of field (the target of the assignment) and the array type of expression (the source for the assignment). For more information, see the Data types reference entry.

- If expression is an ABL handle-based object (for example, a temp-table, ProDataSet, widget, or socket), field must be a temp-table field, variable, or other ABL data element defined as a compatible handle. In this case, the AVM assigns only the handle of the ABL handle-based object to field, not the entire object and its contents.

- If any field is a field in a database record, the ASSIGN statement upgrades the record lock condition to EXCLUSIVE-LOCK before updating the record.

- If any field is part of a record retrieved with a field list, the ASSIGN statement rereads the complete record before updating it.

- If field is a handle, the expression on the right-hand-side of the corresponding assignment must also evaluate to a handle value that is specified using an appropriate reference to a handle-based object handle. For more information on object handle references, see the “Handle Attributes and Methods Reference” section on page 1271.

- During data entry, a validation expression defined for the field in the database or in a Format phrase executes only if the widget associated with the field receives input focus. Use the VALIDATE( ) method to execute a validation expression defined for a field regardless of whether it receives input focus or not.

- Use an ASSIGN statement after a PROMPT-FOR statement or to write changes from an enabled field to the database. ASSIGN moves the value from the screen buffer into the field or variable.
• Use the PROMPT-FOR statement to receive one or more index fields from the user, and you use the FIND statement to find a record matching those index values. If no record is found, use the CREATE statement to create a new record and use the ASSIGN statement to assign the values the user supplied to the new record.

• You cannot use the SET statement in place of the PROMPT-FOR statement. The SET statement prompts the user for input and then assigns that input to the record in the buffer. However, if there is not a record available, SET cannot assign the values.

• ASSIGN does not move data into a field or variable if there is no data in the corresponding screen field. There is data in a screen field if a DISPLAY of the field was done or if data was entered into the field. If you PROMPT-FOR a field or variable that has not been DISPLAYed in the frame and enter blanks, the AVM does not change the field or variable because it considers the screen field changed only if the data differs from what was in the field.

• If an ASSIGN statement references a field or variable that is used in more than one frame, it uses the value in the frame most recently introduced in the procedure.

• If you type blanks into a field that has never displayed data, the ENTERED function returns FALSE and the SET or ASSIGN statement does not update the underlying field or variable. Also, if the AVM marks a field as entered, and the PROMPT-FOR statement prompts for the field again and you do not enter any data, the AVM no longer considers the field entered.

• If you use a single, qualified identifier with the ASSIGN statement, the Compiler interprets the reference as dbname.filename. If the Compiler cannot resolve the reference as dbname.filename, it tries to resolve it as filename.fieldname.

• Many assignments within a single ASSIGN statement are more efficient than multiple ASSIGN statements. It saves r-code size and improves performance.

• The ASSIGN statement, when used in database fields, causes all related database ASSIGN triggers to execute in the order in which the fields were assigned. The ASSIGN triggers execute after all the assignments have taken place. If an ASSIGN trigger fails (or executes a RETURN statement with the ERROR option), all of the database changes are undone.

• You can assign large object data from one BLOB or MEMPTR to another, and from one CLOB, LONGCHAR, or CHARACTER to another. You cannot assign large object data between BLOBs and CLOBs or MEMPTRs and LONGCHARs. You can accomplish, indirectly, by using the COPY-LOB statement. For more information, see the COPY-LOB statement reference entry.

Table 9 lists the default character conversions that the AVM performs when assigning CLOB, LONGCHAR, and CHARACTER data. References to CLOBCP and CLOBDB represent CLOB data in either the CLOB’s defined code page or the database's defined code page, respectively. References to the "fixed code page" represent the code page of a target LONGCHAR variable set using the FIX-CODEPAGE statement.
When you assign the Unknown value (?) to a BLOB or CLOB field, the AVM deletes any associated object data.

You can assign DATE, DATETIME, and DATETIME-TZ data. When the data type expression on the left side of the assignment statement contains more information than the data type expression on the right side provides (for example, `datetime-tz = date` where a DATETIME-TZ value contains more information than a DATE value), the time value defaults to midnight and the time zone value defaults to the session's time zone. When the data type expression on the left side of the assignment statement contains less information than the data type expression on the right side provides (for example, `date = datetime-tz` where a DATE value contains less information than a DATETIME-TZ value), the AVM converts the DATETIME-TZ value to the local date and time of the session, then drops the time and time zone.

If `expression` is a solitary invocation of the NEW function, this function behaves according to the rules specified for the NEW function (classes) when not operating in the context of a NEW statement.

If `expression` evaluates to an object reference value, `field` must also be a data element defined as a class or interface type that is type-compatible with `expression` according to the rules for assigning references to class instances defined for the NEW statement. For more information, see the NEW statement reference entry. Thus, you can assign one object reference variable to another object reference variable when the destination object reference (on the left side of the assignment) is defined for the same class, a super class, or an interface of the object reference being assigned (on the right side of the assignment). The destination object reference retains its defined class or interface type for compilation. However, following its assignment, at run time, the destination represents the subclass of

Table 9: Default character conversions with the ASSIGN statement
field (or the class that implements the interface specified by field) that is defined by expression.

If field has a class type that is a subclass lower in the class hierarchy than the class type represented by expression, you can cast expression to the type of field using the CAST function, but only if expression is a super class that actually contains an instance of the field class type. If field has a class type that implements an interface type represented by expression, you can similarly cast expression using the CAST function, but only if expression actually contains an instance of the field class type. For more information about the CAST function, see the CAST function reference entry.

After the assignment, field contains a copy of the object reference value returned by expression, which points to the same object instance, not a copy of the object referenced by expression.

- Although you can assign an object reference to a temp-table field defined as a Progress.Lang.Object class type, you cannot assign an object reference to a field in a database table. For more information, see OpenEdge Development: Object-oriented Programming.

See also Assignment (=) statement, CAST function, Class-based object reference, COPY-DATASET( ) method, COPY-LOB statement, COPY-TEMP-TABLE( ) method, Data types, Expression, FIX-CODEPAGE statement, INPUT function, PROMPT-FOR statement, SET statement, UPDATE statement

AT phrase

The AT phrase of the Format phrase allows explicit positioning of frame objects, either by row and column or by pixels. The AT phrase of the Frame phrase allows explicit positioning of frames with windows or parent frames.

Syntax

AT \{ COLUMN column | COLUMN-OF reference-point \} \{ ROW row | ROW-OF reference-point \} [ COLON-ALIGNED | LEFT-ALIGNED | RIGHT-ALIGNED ]

AT \{ X x | X-OF reference-point \} \{ Y y | Y-OF reference-point \} [ COLON-ALIGNED | LEFT-ALIGNED | RIGHT-ALIGNED ]

AT n

n

The column, measured in character units. This option is not supported for the Frame phrase. You cannot use the alignment options with this syntax. If you use this option, the AVM chooses the row based on the previous widget and form item layout of the frame. For information on form items, see the DEFINE FRAME statement or FORM statement.
COLUMN column

The column, measured in character units.

COLUMN-OF reference-point

Indicates the column position of the field relative to another field-level widget previously defined in the frame. This option is not supported for the Frame phrase. This is the syntax for reference-point:

**Syntax**

\[
\text{widget} \ [ \{ + | - \} \ offset ]
\]

In this syntax, `widget` is a reference to a field-level widget previously defined in the frame, and `offset` is a positive decimal value. For example, if `widget` is positioned at COLUMN 10, then COLUMN-OF widget + 2.5 positions the field at column 12.5.

X x

The X pixel coordinate.

X-OF reference-point

Indicates the X co-ordinate of the field relative to another field-level widget previously defined in the frame. This option is not supported for the Frame phrase. The co-ordinate is expressed as the co-ordinate of a widget previously defined in the frame, plus or minus an offset. The offset must be either a constant or preprocessor constant and must be a positive integer.

ROW row

The row, measured in character units.

ROW-OF reference-point

Indicates the row of the field relative to another field-level widget previously defined in the frame. This option is not supported for the Frame phrase. The row is expressed as the row of a widget previously defined in the frame, plus or minus an offset. The offset must be either a constant or preprocessor constant and must be a positive decimal value.

Y y

The Y pixel coordinate.

Y-OF reference-point

Indicates the Y co-ordinate of the field relative to another field-level widget previously defined in the frame. This option is not supported for the Frame phrase. The co-ordinate is expressed as the co-ordinate of a widget previously defined in the frame, plus or minus an offset. The offset must be either a constant or preprocessor constant and must be a positive integer.
AUDIT-ENABLED function

Specifies whether a connected database is audit-enabled.

COLON-ALIGNED | LEFT-ALIGNED | RIGHT-ALIGNED

The following example uses the AT phrase to position fields within a frame.

```plaintext
r-at.p
DEFINE FRAME order-info
   Order.CustNum AT ROW 2 COLUMN 8
   Customer.Name AT ROW 2 COLUMN 18
   Order.OrderNum AT ROW 2 COLUMN 50
   Order.OrderDate AT ROW 2 COLUMN 65
WITH TITLE "Order Information".

FOR EACH Order NO-LOCK BREAK BY Order.CustNum WITH FRAME order-info:
   IF FIRST-OF(Order.CustNum) THEN DO:
      FIND Customer OF Order NO-LOCK.
      DISPLAY Order.CustNum Customer.Name.
   END.
   DISPLAY Order.OrderNum Order.OrderDate.
END.
```

The following example uses relative positioning to position fields relative to the CustNum field.

```plaintext
r-at1.p
DEFINE FRAME order-info
   Order.CustNum AT X 50 Y 14
   Customer.Name AT X-OF Order.CustNum + 100 Y 14
   Order.OrderNum AT X-OF Order.CustNum + 225 Y 14
   Order.OrderDate AT X-OF Order.CustNum + 320 Y 14
WITH TITLE "Order Information" NO-LABELS.

FOR EACH Order NO-LOCK BREAK BY Order.CustNum WITH FRAME order-info:
   IF FIRST-OF(Order.CustNum) THEN DO:
      FIND Customer OF Order NO-LOCK.
      DISPLAY Order.CustNum Customer.Name.
   END.
   DISPLAY Order.OrderNum Order.OrderDate.
END.
```

Notes

- The AT phrase does not left justify the data. It simply specifies the position of the data area. If the data is right justified it may appear to be farther right than you expect.
- If you position a child frame completely outside the virtual area of its parent frame, the AVM raises ERROR at run time when the frame is realized.
- For SpeedScript, you can position objects by row or column, not by pixels.

DEFINE FRAME statement, FORM statement, Frame phrase

AUDIT-ENABLED function

Determines whether a connected database is audit-enabled.
For information about audit-enabling a database, or creating and activating an audit policy for a database, see *OpenEdge Getting Started: Core Business Services*.

**Syntax**

```
AUDIT-ENABLED( [ integer-expression | logical-name | alias ] )
```

*integer-expression*

The sequence number of a connected database to query. For example, AUDIT-ENABLED(1) queries the first database, AUDIT-ENABLED(2) queries the second database, and so on. If you specify a sequence number that does not correspond to a connected database, the AVM returns the Unknown value (?).

*logical-name or alias*

The logical name or alias of a connected database to query. These forms require a quoted character string or a character expression. If you specify a logical name or alias that does not correspond to a connected database, the AVM returns the Unknown value (?).

**Notes**

- If you specify a connected database, the AVM queries that database and returns TRUE if it is audit-enabled. If you do not specify a database, the AVM queries all connected databases and returns TRUE if any one of the connected databases is audit-enabled.

- You can reference the AUDIT-ENABLED function within a preprocessor &IF expression (such as, &IF AUDIT-ENABLED … &ENDIF). For more information, see the &IF, &THEN, &ELSEIF, &ELSE, and &ENDIF preprocessor directives reference entry.

**See also**

AUDIT-POLICY system handle

---

**AVAILABLE function**

Returns a TRUE value if the record buffer you name contains a record and returns a FALSE value if the record buffer is empty.

When you use the FIND statement or the FOR EACH statement to find a record, the AVM reads that record from the database into a record buffer. This record buffer has the same name as the file used by the FIND or FOR EACH statement, unless you specify otherwise. The CREATE statement creates a new record in a record buffer.

**Syntax**

```
AVAILABLE record
```

*record*

The name of the record buffer you want to check.

**Note:** To access a record in a table defined for multiple databases, you might have to qualify the record’s table name with the database name. See the Record phrase reference entry for more information.
AVAILABLE function

**Example**

In this procedure, the FIND statement with the NO-ERROR option bypasses the default error checking and does not display the message you get. Because ItemNum is unique, you do not have to use the AMBIGUOUS function to pinpoint the cause of a record not being AVAILABLE.

```plaintext
r-avail.p

REPEAT:
  PROMPT-FOR Item.ItemNum.
  FIND Item USING ItemNum NO-ERROR.
  IF AVAILABLE Item THEN
    DISPLAY Item.ItemName Item.Price.
  ELSE
    MESSAGE "Not found".
  END.
```

**See also**

AMBIGUOUS function, FIND statement, FOR statement, LOCKED function, NEW function (record buffers)
BASE64-DECODE function

Converts a Base64 character string into a binary value. The result is a MEMPTR containing the binary data.

Syntax

BASE64-DECODE ( expression )

expression

A CHARACTER or LONGCHAR expression containing the string you want to convert.

Example

Following is an example using the BASE64-DECODE function:

```clipped
DEFINE VARIABLE decdmptr AS MEMPTR NO-UNDO.
DEFINE VARIABLE decdlngc AS LONGCHAR NO-UNDO.
COPY-LOB FROM FILE "C:\myicons\testencode" TO decdlngc.
decdmptr = BASE64-DECODE(decdlngc).
COPY-LOB FROM decdmptr TO FILE "C:\myicons\test.ico".
```

BASE64-ENCODE function

Converts binary data into a Base64 character string, and returns a LONGCHAR containing the character data. The resulting LONGCHAR is in the code page specified by -cpinternal.

Syntax

BASE64-ENCODE ( expression )

expression

A MEMPTR or RAW expression containing the binary data you want to convert.

Example

Following is an example using the BASE64-ENCODE function:

```clipped
DEFINE VARIABLE encdmptr AS MEMPTR NO-UNDO.
DEFINE VARIABLE encdlngc AS LONGCHAR NO-UNDO.
COPY-LOB FROM FILE "C:\myicons\test.ico" TO encdmptr.
encdlngc = BASE64-ENCODE(encdmptr).
COPY-LOB FROM encdlngc TO FILE "C:\myicons\testencode".
```

BEGINS operator

Tests a character expression to see if that expression begins with a second character expression.

Syntax

expression1 BEGINS expression2
**BEGINS operator**

expression1

An expression that has a CHARACTER or LONGCHAR value that you test to see if it begins with expression2.

expression2

An expression that has a character value that you want to compare to the beginning of expression1. If you specify a null value (""") for expression2, the AVM returns all the records in the database.

**Examples**

In this procedure, the user supplies a customer name or the first characters of a customer name. The procedure finds customer records where the name field begins with the user’s input. If the customer file is indexed on the name field, this procedure is very efficient and retrieves only the selected records.

**r-bgns.p**

```abl
DEFINE VARIABLE cName NO-UNDO LIKE customer.name LABEL "Name".
REPEAT:
   SET cName WITH SIDE-LABELS.
   FOR EACH Customer NO-LOCK WHERE Customer.Name BEGINS cName:
   END.
END.
```

The next procedure lists exactly the same customers. However, it is much less efficient because it retrieves and examines all customer records, and only displays the ones with the appropriate names.

**r-bgns2.p**

```abl
DEFINE VARIABLE cName NO-UNDO LIKE customer.name LABEL "Name".
REPEAT:
   SET cName WITH SIDE-LABELS.
   /* Create MATCHES pattern */
   cName = cName + "*".
   FOR EACH Customer NO-LOCK WHERE Customer.Name MATCHES cName:
   END.
END.
```

**Notes**

- The BEGINS operator is double-byte enabled. You can use the BEGINS operator to compare strings containing double-byte characters.
- When you use the BEGINS operator to compare LONGCHAR fields, BEGINS always uses the -cpcoll collation.
- BEGINS is useful in a WHERE phrase that specifies which records should be retrieved in a FOR EACH block. Unlike the MATCHES operator, which requires that all records in the file be scanned, BEGINS uses an index wherever possible.
- Most character comparisons are case insensitive in ABL. By default, all characters are converted to uppercase prior to comparisons. However, you can define fields and variables
as case sensitive (use if strict ANSI SQL adherence is required). If either of the character expressions passed to BEGINS is a field or variable defined as case sensitive, the comparison is case sensitive. In a case-sensitive comparison “SMITH” does not equal “Smith”.

• ABL considers trailing blanks in the BEGINS operator. For example, this statement is FALSE:

```
"x" BEGINS "x     
```

This is different than comparisons, where trailing blanks are ignored. For example, this statement IS TRUE:

```
"x" = "x     
```

See also MATCHES operator

## BELL statement

Causes the terminal to make a beep sound.

**Note:** Does not apply to SpeedScript programming.

### Syntax

```
BELL
```

### Example

The following procedure dynamically determines the output file to use for a report that lists all customer records. The SET statement gets the name of a file from the user. The SEARCH function returns an unqualified file name if that file already exists in your working directory. If the file exists in your working directory, it displays messages, undoes the work done in the DO block, and lets the user enter another file name. (The procedure determines whether the file is in your working directory. If SEARCH returns a directory other than your current working directory, you receive no messages and it does not undo your work.) After you type a file name that does not already exist, the OUTPUT TO statement directs the output of the procedure to that file.
BOX function

(Windows only; GUI for .NET only)

Returns an object reference to a .NET System.Object that contains (boxes) a .NET mapping of an ABL value. At run time, this mapping depends on the kind of ABL value passed to the function. If you pass an ABL primitive value, the function returns a corresponding .NET mapped object type. If you pass an ABL array of .NET-compatible elements, the function returns a corresponding .NET array object type.

Syntax

```
BOX ( ABL-expression [ , AS-data-type-expression ] )
```

**ABL-expression**

Specifies an expression that specifies one of the following .NET-compatible ABL data types:

- CHARACTER
- DATE
- DATETIME
- DATETIME-TZ
- DECIMAL
- INT64
- INTEGER
- LOGICAL

**Note**

If the terminal is not the current output device, BELL has no effect.
• LONGCHAR

• A .NET-compatible ABL array

A .NET-compatible ABL array is an ABL array of one of the listed ABL primitive types or an ABL array of any supported .NET object type (a .NET object type not mapped as specified in Table 23).

AS-data-type-expression

If ABL-expression is an ABL primitive type, this is a character expression equal to a keyword (AS data type) that matches the explicit .NET mapped data type into which you want to box the specified ABL-expression. If ABL-expression is an ABL primitive array, the character expression is an AS data type that specifies the explicit .NET mapped data type that the elements of the array should be converted to in the resulting .NET array object. This AS data type must correspond to one of the .NET types that maps appropriately to the ABL primitive type (or array element type) of ABL-expression (see Table 24).

If you do not specify AS-data-type-expression and ABL-expression is an ABL primitive (or primitive array), ABL boxes ABL-expression using the default matching .NET type that corresponds to the ABL primitive type (or array element type) of ABL-expression.

This option has no meaning when ABL-expression is an ABL array of a supported .NET object type.

Example

The following code creates a .NET DataTable with a single DataRow containing two columns. It then adds data to the row for the two columns. The Item indexed property used to access the columns has the data type System.Object. So, to add data to each column, you might have to use the BOX function to box the specified ABL value into an appropriate System.Object instance for the column. For example:
Notes

• For many direct assignments of a System.Object to an ABL primitive value or .NET-compatible ABL array, use of the BOX function is optional, because ABL automatically boxes the assigned ABL value into its default matching .NET object type. However, one such assignment for which you must use the BOX function is when you want to box an ABL primitive value (or primitive array) as a valid .NET mapped data type (or array of mapped types) other than the default match, for example, when boxing an ABL INTEGER (or INTEGER EXTENT) as a .NET System.Byte (or "System.Byte[]").

• If you pass a compatible ABL value or array to an INPUT parameter of a .NET method, ABL automatically boxes the ABL value into the matching .NET System.Object or array object. For an ABL primitive (or primitive array) value, this automatic boxing also allows you to explicitly specify the .NET data type mapping if you use the AS data type option on the ABL argument that you pass to the INPUT parameter (see the Parameter passing syntax reference entry). This automatic boxing does not occur for an ABL method, procedure, or user-defined function passing the same parameters. In this case, you can do an initial direct assignment or use the BOX function to explicitly do the necessary conversion.

See also Data types, UNBOX function

BUFFER-COMPARE statement

Performs a bulk comparison of two records (source and target) by comparing source and target fields of the same name for equality and storing the result in a field. You can specify a list of fields to exclude, or a list of fields to include. You can also specify WHEN...THEN phrases. For all such phrases you specify, the AVM evaluates the WHEN portion, and if it evaluates to TRUE, the AVM executes the THEN portion.
Syntax

```
BUFFER-COMPARE source
   [ { EXCEPT | USING } field ... ] TO target
   [ CASE-SENSITIVE | BINARY ]
   [ SAVE [ RESULT IN ] result-field ]
   [ [ EXPLICIT ] COMPARES ]:
      [ WHEN field compare-operator expression
          THEN statement-or-block ] ...
   [ END [ COMPARES ] ] [ [ NO-LOBS ] [ NO-ERROR ] ]
```

**source**

The source database table, buffer, temp-table, or work table.

**EXCEPT field**

A list of source fields to exclude from the bulk compare.

**USING field**

A list of source fields to include in the bulk compare. The USING option is a positive version of the EXCEPT option.

**TO target**

The target database table, buffer, temp-table, or work table.

**CASE-SENSITIVE**

Directs the AVM to perform a case-sensitive comparison.

**BINARY**

Directs the AVM to perform a binary comparison.

**SAVE RESULT IN result-field**

A variable or field to contain the result of the comparison. The variable or field must be CHARACTER or LOGICAL.

If `result-field` is CHARACTER, the result is a comma-separated list of fields that failed the comparison, sorted in ascending order.

If `result-field` is LOGICAL, the result is YES if all fields are equal, or NO if any fields are unequal. In either case, BUFFER-COMPARE stops comparing when it encounters the first inequality.

**EXPLICIT COMPARES**

Opens a block of WHEN options. If you open the block, you must close it with END COMPARES.

**WHEN field**

Any data field in the source.
BUFFER-COMPARE removes this field from a USING list or adds this field to an EXCEPT list. This removes the field from the bulk compare and from result-field.

\textit{compare-operator}

Represents one of the following: LT, LE, GT, GE, EQ, NE, MATCHES, BEGINS, or CONTAINS.

\textit{expression}

Any valid ABL expression.

THEN \textit{statement-or-block}

Any ABL statement or block. The statement or block executes when the \textit{WHEN} clause evaluates to TRUE.

END COMPARES

Closes the block of \textit{WHEN} phrases.

\textbf{NO-LOBS}

Directs the AVM to ignore large object data when comparing records that contain BLOB or CLOB fields.

---

\textbf{Caution:} When using this option, you get no warning if a LOB field has changed. This can lead to inappropriate results. Therefore, before using this option, you must understand the nature of your data and be sure that logic using this option will not result in inconsistent or out-of-date data in the database.

---

\textbf{NO-ERROR}

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the \textbf{ERROR-STATUS system handle}. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block \textbf{without} a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block \textbf{with} a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.
• Use ERROR-STATUS:GET-MESSAGE(message-num) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

• NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

• A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

• When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

• If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

Notes

• At compile time, BUFFER-COMPARE:
  – Fails to compile if any source-target field pair is not type compatible. An example of such a pair is a field that is LOGICAL in the source, but DECIMAL in the target.
  – Excludes from the bulk comparison all EXCEPT field fields and all WHEN field fields.
  – Automatically excludes from the bulk comparison fields that appear in the source but not in the target.
  – Tries to bind unqualified field names that appear in the EXCEPT and USING options to the source buffer.

• At run time, BUFFER-COMPARE:
  – Compares all fields not in the EXCEPT phrase and all fields not in the WHEN phrase for equality
  – Stores the result in the field that the SAVE phrase specifies, if any
  – Evaluates each WHEN option, executing it if its condition evaluates to TRUE
Note: This behavior is different from the behavior of the ABL CASE statement, which executes only the first WHEN option whose condition evaluates to TRUE.

- When comparing records that contain BLOB fields, the AVM performs a binary comparison on the BLOB data associated with the source and target records, and reports the results of the comparison.

- You cannot use the BUFFER-COMPARE statement to compare records that contain CLOB fields, unless one or both of the corresponding fields contain the Unknown value (?). However, you can convert CLOB fields to LONGCHAR values and use the EQ, GE, GT, LE, LT, or NE comparison operator to compare the LONGCHAR values.

- Use the NO-LOBS option with the BUFFER-COMPARE statement to ignore large object data when comparing records that contain BLOB or CLOB fields. You can also use the EXCEPT option to exclude BLOB and CLOB fields from the compare.

See also BUFFER-COPY statement

BUFFER-COPY statement

Performs a bulk copy of a source record to a target record by copying each source field to the target field of the same name. You can specify a list of fields to exclude from the bulk copy, or a list of fields to include in the bulk copy. You can also specify WHEN...THEN phrases. For each such phrase, BUFFER-COPY executes the THEN portion if the corresponding WHEN portion evaluates to TRUE.

Syntax

```
BUFFER-COPY source [ { EXCEPT | USING } field ... ] TO target [ ASSIGN assign-expression ... ] [ NO-LOBS ] [ NO-ERROR ]
```

source

The source database table, buffer, temp-table, or work table.

EXCEPT field ...

A list of space-separated source fields to exclude from the bulk copy.

USING field ...

A list of space-separated source fields to include in the bulk copy. The USING option is simply a positive version of the EXCEPT option.

TO target

The source database table, buffer, temp-table, or work table.

ASSIGN assign-expression

A space-separated list of any valid ABL ASSIGN statements (without the EXCEPT option, which BUFFER-COPY already provides). BUFFER-COPY performs each
**BUFFER-COPY statement**

*assign-expression* and automatically excludes the field on the left side ("destination") of each *assign-expression* from the bulk copy except for field extents (subscripted fields). If a field extent appears on the left side of an *assign-expression*, BUFFER-COPY does not automatically exclude that extent (such as customer.mnth-sales[1]) or the field as a whole (such as customer.mnth-sales) from the bulk copy.

**NO-LOBs**

Directs the AVM to ignore large object data when copying records that contain BLOB or CLOB fields.

**Caution:** Using this option can create the potential for errors in your data and lead to inappropriate results. Therefore, before using this option, you must understand the nature of your data and be sure that logic using this option will not result in inconsistent or out-of-date data in the database.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block
of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

Notes

- At compile time, BUFFER-COPY:
  - Fails to compile if any source-target field pair is not type compatible
  - Excludes from the bulk copy all EXCEPT field fields, and all assign-expression fields on the left side of the assignment
  - Automatically excludes fields that appear in the source but not the target from the bulk copy
  - Tries to bind unqualified field names that appear in the EXCEPT and USING options to the source buffer

- At run time, BUFFER-COPY:
  - Creates a target record if none already exists and executes any applicable CREATE triggers
  - Assigns all matching fields that do not appear in the EXCEPT or ASSIGN options
  - Performs each assign-expression in the ASSIGN option, one-by-one

- The BUFFER-COPY statement, like the VALIDATE statement, must appear within the scope of a FIND, a FOR EACH, or a CREATE statement that references the source table.

- If a BUFFER-COPY statement references a target buffer for the first time, ABL regards this reference as a “free reference” and scopes the buffer to the nearest enclosing block that can scope records. For more information on free references, see the chapter on block properties in OpenEdge Getting Started: ABL Essentials.

- With respect to transaction processing, ABL treats a BUFFER-COPY statement the same way it would treat equivalent ASSIGN statements. For more information on transaction processing, see the chapter on transactions in OpenEdge Getting Started: ABL Essentials.

- The compiler’s XREF facility automatically creates a REFERENCE for each field in the fields list, a TABLE-REFERENCE for the source and target buffers, ACCESS and
UPDATE references for any fields in the ASSIGN option, and ACCESS (or UPDATE) references for each source (or target) field that participates in the bulk copy.

- When copying records that contain a BLOB or CLOB field, the AVM copies the object data associated with the source record to the target record. If the BLOB or CLOB field in the source record contains the Unknown value (?), the AVM stores the Unknown value (?) in the BLOB or CLOB field of the target record. If the target record already has object data associated with it, the AVM deletes that object data before copying the new object data.

- Use the NO-LOBS option with the BUFFER-COPY statement to ignore large object data when copying records that contain BLOB or CLOB fields. More specifically:
  - When you copy a source record to a new target record, the AVM sets the value of the BLOB or CLOB field in the target record to the Unknown value (?).
  - When you copy a source record to an existing target record, the AVM does not change the value of the BLOB or CLOB field in the existing target record.

You can also use the EXCEPT option to exclude BLOB and CLOB fields from the copy.

See also BUFFER-COMPARE statement
CALL Statement

Transfers control to a dispatch routine (PRODSP) that then calls a C function. You write the C function using ABL Host Language Call (HLC) interface.

ABL HLC consists of a collection of C functions that:

- Obtain data from ABL shared variables and buffers
- Set data in ABL shared variables and buffers
- Control screen modes
- Provide ABL-like messages in the message area at the bottom of the screen

Using HLC, you can extend ABL with your own C functions.

Syntax

```
CALL routine-identifier [ argument ] ...
```

**routine-identifier**

The name the PRODSP dispatch routine used to identify the C function to call.

**argument**

One or more arguments that you want to pass to the C function.

See also

RUN statement

CAN-DO function

Checks a string value against two types of comma-separated lists:

- An ID list of one or more user permission strings that indicate what users have access to the current procedure. The function returns TRUE if the specified user ID has access according to the list. Thus, you can implement run-time authorization for any procedure in your application.
- An arbitrary list of string values. The function returns TRUE if the specified string value is contained in the list.

Syntax

```
CAN-DO ( id-list [ , string ] )
```

**id-list**

A constant, field name, variable name, or expression that evaluates to a list of one or more user IDs. If the expression contains multiple user IDs, you must separate the user IDs with commas. Do not insert blanks between the user IDs.

Table 10 lists values you can use in *id-list*.  

---

76
**Table 10: Values to use for ID lists**

<table>
<thead>
<tr>
<th>Value</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>*</td>
<td>All users have access.</td>
</tr>
<tr>
<td>user</td>
<td>This user has access.</td>
</tr>
<tr>
<td>!user</td>
<td>This user does not have access.</td>
</tr>
<tr>
<td>string*</td>
<td>Users whose IDs begin with string have access.</td>
</tr>
<tr>
<td>!string*</td>
<td>Users whose IDs begin with string do not have access.</td>
</tr>
</tbody>
</table>

You can use any combination of values to define id-list, and you must separate the values with commas.

*string*

A character expression. The string is checked against id-list. If you do not enter string, the compiler inserts the USERID function that is evaluated each time you run the procedure. If the compiler inserts the USERID function, it does not reference a database name. If you use the USERID function and have more than one database connected, be sure to include the database name, for example, USERID “demo”.

**Examples**

The r-cando.p procedure is based on an activity permission table called permission. The permission table is not included in your demo database. However, the records in that table might look something like the following:

<table>
<thead>
<tr>
<th>Activity</th>
<th>Can-Run</th>
</tr>
</thead>
<tbody>
<tr>
<td>custedit</td>
<td>manager,salesrep</td>
</tr>
<tr>
<td>ordedit</td>
<td>manager,salesrep</td>
</tr>
<tr>
<td>itemedit</td>
<td>manager,inventory</td>
</tr>
<tr>
<td>reports</td>
<td>manager,inventory,salesrep</td>
</tr>
</tbody>
</table>

In r-cando.p the FIND statement reads the record for the activity custedit in the permission table. (This assumes that a unique primary index is defined on the activity field.) The CAN-DO function compares the user ID of the user running the procedure with the list of users in the can-run field of the custedit record. If the user ID is manager or salesrep, the procedure continues executing. Otherwise, the procedure displays a message and control returns to the calling procedure.

**r-cando.p**

```
DO FOR permission:
    FIND permission "custedit".
    IF NOT CAN-DO(permission.can-run) THEN DO:
        MESSAGE "You are not authorized to run this procedure".
        RETURN.
    END.
END.
```
In this next example, the CAN-DO function compares \texttt{userid} (the user ID for the current user) against the values in \texttt{id-list}. The values in \texttt{id-list} include manager and any user IDs beginning with acctg except acctg8. If there is no match between the two values, the procedure displays a message and then exits.

\begin{verbatim}
r-cando2.p
IF NOT CAN-DO("manager,!acctg8,acctg*") THEN DO:
   MESSAGE "You are not authorized to run this procedure.".
   RETURN.
END.
\end{verbatim}

In addition to performing security checks, you can use the CAN-DO function for looking up any value in a comma-separated list. For example, the following procedure searches your \texttt{PROPATH} for your DLC directory:

\begin{verbatim}
r-cando3.p
MESSAGE "The DLC directory " +
   (IF CAN-DO(PROPATH, OS-GETENV("DLC")) THEN "is" ELSE "is NOT") +
   " in your PROPATH.".
\end{verbatim}

\textbf{Notes}

- If \texttt{id-list} contains contradictory values, the first occurrence of a value in the list applies. For example, CAN-DO(“abc,!abc*”, “abc”) is TRUE, since the user ID abc appears before !abc in \texttt{id-list}.
- If \texttt{id-list} is exhausted without a match, CAN-DO returns a value of FALSE. Therefore, !abc restricts abc and everyone else (including the blank userid, “”). To restrict abc only and allow everyone else, use !abc,*.
- A \texttt{userid} comparison against \texttt{id-list} is not case sensitive.
- If a user is logged into the system as root, the AVM allows access to the procedure even if access is denied by the \texttt{id-list}. You must specifically deny root access by adding !root to the \texttt{id-list}.
- In addition to the examples shown above, you can use the CAN-DO function to compare a \texttt{userid} other than that of the current user against the list of values in \texttt{id-list}. For example, to assign a department \texttt{userid} to users “smith” and “jones” when they start the ABL session, you can prompt these users for a department \texttt{userid} and \texttt{password}. The AVM then compares the supplied information against a table of identifiers.

If the values supplied by the user match those in the identifier table, you can define a global shared variable for the AVM to use for the entire session. The value of this variable is the department \texttt{userid}. The AVM uses the CAN-DO function to compare \texttt{userid} (the value of the global shared variable) against the list of values in \texttt{id-list}.

If you know the name of the global shared variable, you can define another variable with the same name and call subroutines directly.

- You establish user IDs with the USERID and SETUSERID functions, or with the Userid (-U) and Password (-P) startup parameters. The user ID can be an operating system user ID (on UNIX) or a user ID stored in the _User table (in Windows or on UNIX).
- ABL returns a compiler error if you omit `userid` and one of the following conditions exists:
  - There is no database connected.
  - More than one database is currently connected.

- CAN-DO outside of a VALIDATE statement is the same as FIND ... NO-ERROR followed by IF AVAILABLE(...).

**See also**
SETUSERID function, USERID function, VALIDATE statement

### CAN-FIND function

Returns a TRUE value if a record is found that meets the specified FIND criteria; otherwise it returns FALSE. CAN-FIND does not make the record available to the procedure. You typically use the CAN-FIND function within a VALIDATE option in a data handling statement, such as the UPDATE statement.

You can use CAN-FIND to see if a record exists with less system overhead than that of a FIND statement. The query capabilities are similar. CAN-FIND is also useful for implementing inner joins among database tables.

#### Syntax

```
CAN-FIND
(  
    [ FIRST | LAST ] record [ constant ]
    [ OF table ] [ WHERE expression ] [ USE-INDEX index ]
    [ USING [ FRAME frame ] field
      [ AND [ FRAME frame ] field ] ... ]
    [ SHARE-LOCK | NO-LOCK ] [ NO-WAIT ] [ NO-PREFETCH ]
)
```

You can specify the OF, WHERE, USE-INDEX, and USING options in any order.

**FIRST**

Returns TRUE if CAN-FIND locates a record that meets the specified criteria; otherwise returns FALSE.

**LAST**

Returns TRUE if CAN-FIND locates a record that meets the specified criteria; otherwise returns FALSE.

**record**

The record buffer you are checking for existence.

To use CAN-FIND to locate a record in a table defined for multiple databases, you might have to qualify the record’s table name with the database name. See the Record phrase reference entry for more information.
**CAN-FIND function**

constant

The table you want to use has a primary index; the constant is the value of the last component field of that index for the record you want.

OF table

Qualifies the records to use by relating the record to a record in another table.

WHERE expression

Qualifies the record that CAN-FIND searches for. The expression must return a TRUE or FALSE value.

USE-INDEX index

Identifies the index you want CAN-FIND to use to find a record. If you do not use this argument, the AVM selects an index to use based on the criteria specified with the WHERE, USING, OF, or constant arguments.

USING [ FRAME frame ] field [ AND [ FRAME frame ] field ]

One or more names of fields you want to use to search for a record. The field you name in this argument must have been previously entered into a screen field, usually with a PROMPT-FOR statement. The field must be viewed as a fill-in or text widget.

SHARE-LOCK

Specifies that CAN-FIND determines whether the record can be SHARE-LOCKed. If you use this option without the NO-WAIT option, and if the record is EXCLUSIVE-LOCKed, CAN-FIND waits until that lock is released before returning. If you use SHARE-LOCK with the NO-WAIT option, then CAN-FIND returns a FALSE value immediately if the record is EXCLUSIVE-LOCKed.

NO-LOCK

Specifies that CAN-FIND determines whether the record can be accessed with the NO-LOCK option. This is the default for CAN-FIND.

NO-WAIT

Causes CAN-FIND to return immediately and return FALSE if the record is locked by another user.

If you use NO-WAIT together with a SHARE-LOCK and the record found is EXCLUSIVE-LOCKed, the CAN-FIND function does not wait and returns FALSE.

NO-PREFETCH

Specifies that only one record can be sent across the network at a time. If you do not specify this option, the AVM might send more than one record from the server to the client in each network packet.

**Example**

In the following procedure, the UPDATE statement uses the VALIDATE option to make sure that the salesrep entered matches one of the salesreps in the database. The VALIDATE option uses the CAN-FIND function to find the record.
**CAN-FIND function**

**Notes**

- Fields do not have to be indexed to use them in a CAN-FIND function. For example, you can use the following CAN-FIND function with the `sports2000` database, even though the `State` field is not indexed:

  ```plaintext
  CAN-FIND(FIRST Customer WHERE Customer.State = "NH")
  ````

  However, when you use CAN-FIND on a non-indexed field, the response might be slow, as with a FIND.

- You can name more than one field as part of the selection criteria. For example, the following CAN-FIND function works with the `sports2000` database:

  ```plaintext
  CAN-FIND(Customer WHERE Customer.CustNum = x AND Customer.Name = y)
  ````

- CAN-FIND supports selection criteria that uses inequality matches. Therefore, you can use Boolean operations in WHERE clauses.

- EXCLUSIVE lock is not allowed in a CAN-FIND because CAN-FIND does not return a record.

- If you use the CAN-FIND function to find a record in a work table, the AVM disregards the NO-WAIT, SHARE-LOCK, and NO-LOCK options.

- You can nest CAN-FIND functions. For example, you can use CAN-FIND(... WHERE CAN-FIND(...WHERE CAN-FIND, etc.

- The CAN-FIND function does not cause FIND triggers to execute; hence a procedure can use this function to bypass the FIND trigger and check for the existence of records. Anyone writing a FIND trigger for security reasons should be aware of this.

- You cannot use the CAN-FIND function in a query’s WHERE clause. Doing so generates a compiler error.

- Within a CAN-FIND function, if you compare tables or fields from multiple databases, you must explicitly specify the database name along with the table and field name.

**See also**

FIND statement
CAN-QUERY function

Returns a logical value indicating whether you can query a specified attribute or method for a specified widget.

Syntax

```
CAN-QUERY ( handle, attribute-name )
```

**handle**

An expression that evaluates to a handle. The handle must refer to a valid widget.

**attribute-name**

An expression that evaluates to a character-string value. The contents of the string must be an attribute or method name. For more information on attributes, see the “Handle Attributes and Methods Reference” section on page 1271.

Example

The following example prompts for a widget type and an attribute. It creates a widget of the specified type and passes a handle to that widget and the attribute you specified to the CAN-QUERY and CAN-SET functions. Then it reports whether the attribute can be queried or set for that widget.

```
DEFINE VARIABLE attribute AS CHARACTER NO-UNDO FORMAT "x(24)"
LABEL "Attribute".
DEFINE VARIABLE queryable AS LOGICAL NO-UNDO VIEW-AS TOGGLE-BOX
LABEL "Query".
DEFINE VARIABLE setable AS LOGICAL NO-UNDO VIEW-AS TOGGLE-BOX
LABEL "Set".
DEFINE VARIABLE temp-handle AS HANDLE NO-UNDO.
DEFINE VARIABLE widget-type AS CHARACTER NO-UNDO FORMAT "x(24)"
LABEL "Widget".

FORM widget-type attribute setable queryable.

REPEAT:

UPDATE widget-type attribute.
CREATE VALUE(widget-type) temp-handle.
queryable = CAN-QUERY(temp-handle, attribute).
setable = CAN-SET(temp-handle, attribute).
DISPLAY queryable setable.
DELETE WIDGET temp-handle.
END.
```

Note

For SpeedScript, use with buffer-field, buffer-object, buffer, and query-object handles.

See also

CAN-SET function, LIST-QUERY-ATTRS function, LIST-SET-ATTRS function

CAN-SET function

Returns a logical value indicating whether you can set a specified attribute for a specified widget.
CAPS function

Converts any lowercase characters in a CHARACTER or LONGCHAR expression to uppercase characters, and returns the result.

Syntax

CAPS ( expression )

expression

A constant, field name, variable name, or expression that results in a CHARACTER or LONGCHAR value.

Example

In the following code example, the CAPS function converts the characters in the state field to uppercase:

r-caps.p

REPEAT:
PROMPT-FOR Customer.CustNum.
FIND Customer USING Customer.CustNum.
DISPLAY Customer.State.
END.
CASE statement

Notes

- The CAPS function returns uppercase characters relative to the settings of the Internal Code Page (-cpinternal) and Case Table (-cpcase) startup parameters. For more information on these parameters, see OpenEdge Deployment: Startup Command and Parameter Reference.

- The CAPS function is double-byte enabled. The specified expression can yield a string containing double-byte characters; however, the CAPS function changes only single-byte characters in the string.

See also

LC function

CASE statement

Provides a multi-branch decision based on the value of a single expression.

Syntax

```
CASE expression :
    { WHEN value [ OR WHEN value ] ... THEN
        { block | statement }
    } ... 
    [ OTHERWISE
        { block | statement }
    ]
END [ CASE ]
```

expression

The expression that determines which branch of code to execute. The expression parameter can be any valid ABL expression. It can include comparisons, logical operations, and parentheses.

```
WHEN value [ OR WHEN value ] ... THEN
```

Each value is an expression that evaluates to a possible value for expression. If value matches the current value of expression, then the associated block or statement executes.

```
OTHERWISE
```

Introduces a block or statement to execute when the value of expression does not match any value in any of the WHEN clauses.

block

A DO, FOR, or REPEAT block. If you do not use a block, then you can only use a single statement for the WHEN or OTHERWISE clause.

statement

A single ABL statement. If you want to use more than one statement, you must enclose them in a DO, FOR, or REPEAT block.
END [ CASE ]

Indicates the end of the CASE statement. You can include the CASE keyword here to improve readability; it has no effect on the code.

Example

The following fragment shows a simple example of a CASE statement:

**r-case.p**

```plaintext
DEFINE VARIABLE pay-stat AS INTEGER NO-UNDO INITIAL 1.
UPDATE pay-stat VIEW-AS RADIO-SET
  RADIO-ITEM unpaid   1 LABEL "Unpaid"
  RADIO-ITEM part     2 LABEL "Partially paid"
  RADIO-ITEM paid     3 LABEL "Paid in full".
CASE pay-stat:
  WHEN 1 THEN
    MESSAGE "This account is unpaid.".
  WHEN 2 THEN
    MESSAGE "This account is partially paid.".
  WHEN 3 THEN
    MESSAGE "This account is paid in full.".
END CASE.
```

Notes

- Each value must have the same data type as expression. If the data types do not match, the compiler reports an error.

- You can specify any number of WHEN clauses within the CASE statement.

- You can specify only one OTHERWISE clause for a CASE statement. If you use the OTHERWISE clause, it must be the last branch in the statement.

- When a CASE statement is executed, the AVM evaluates expression and evaluates each value for each branch in order of occurrence until it finds the first value that satisfies the condition. At that point the AVM executes that branch and does not evaluate any other value for that branch or any other branches. If no matching value is found, then the OTHERWISE branch is executed, if given. If the OTHERWISE branch is not given and no matching value is found, then no branch of the CASE statement is executed and execution continues with the statement after the CASE statement.

- After a branch of the CASE statement is executed, the AVM leaves the CASE statement and execution continues with the statement following the CASE statement.

- If a LEAVE statement is executed within any branch of a CASE statement, the AVM leaves the closest block (other than a DO block) that encloses the CASE statement.

**CAST function**

Returns a new object reference to the same class instance as an existing object reference, but with a different data type. This different data type is cast from the object type of the original object reference according to another specified object type. The two object types must be related, where one is a class type and the other is a subclass of that class type or where one is an interface type and the other is a class that implements the interface of that type.
When you cast an object reference, ABL treats it as if it referenced an instance of the object type to which it is cast. The underlying class hierarchy of the object instance does not change.

**Syntax**

```plaintext
CAST( object-reference, object-type-name ).
```

- `object-reference`  
  An object reference defined with the object type to be cast.

- `object-type-name`  
  Specifies the type name of an ABL or .NET class or interface type to which the object reference is cast. This object type must be a class type in a class hierarchy that includes or implements the `object-reference` data type or it must be an interface type that the `object-reference` data type implements. Specify the object type name using the syntax described in the [Type-name syntax reference entry](#). With an appropriate USING statement, you can also specify an unqualified class or interface name alone.

**Notes**

- You typically cast an object reference down a class hierarchy—that is, from a super class to a derived class within a class hierarchy, or from an interface to a class that implements that interface. However, you do not always need to explicitly cast an object reference. Because a derived class contains all the super classes in its inherited class hierarchy, ABL implicitly casts any object reference up within its class hierarchy, and because a class that implements an interface implements all of the methods specified for the interface, ABL implicitly casts any object reference from an implementing class to any interface that the class implements.

- At compile time, ABL verifies that the specified object type is within the class hierarchy of the specified object reference. At run time, the AVM checks the validity of the cast operation. Therefore, if you access a class member on the cast object reference that exists for the cast data type, but the referenced object at run time does not actually define the accessed class member, the AVM raises ERROR at run time.

- A .NET generic type can be part of a cast. For example, you can cast from a `System.Object` to a "System.Collections.Generic.List<SHORT>", because all .NET classes, including generic classes, derive from the .NET root class. However, note that you cannot cast from a "System.Collections.Generic.List<System.Object>" to a "System.Collections.Generic.List<System.Windows.Forms.Button>". You cannot assign a "List<Button>" reference to an object reference defined as a "List<Object>", because, even though the type parameters are compatible, the two objects as a whole are not equivalent and have no inheritance relationship. Therefore, a cast between these two objects cannot work either. For more information on .NET generic types, see the [Data types reference entry](#).

- You can also use the **DYNAMIC-CAST function** to cast object references to object types determined at run time. This is especially useful in object-oriented applications that conform to the OpenEdge Reference Architecture (OERA). For more information on the OERA, see the Progress Software Developers Network (PSDN): [http://communities.progress.com/pcom/community/psdn](http://communities.progress.com/pcom/community/psdn).

- You can use the **CAST function** to cast a parameter in a parameter list for a method using the following syntax:
You can use the CAST function to cast a temp-table field, which is defined as a Progress.Lang.Object, to use as an object of another class type. For example:

```abl
DEFINE VARIABLE rCustObj AS CLASS acme.myObjs.CustObj.
```

You can now use the object reference in `rCustObj` to invoke methods in the `acme.myObjs.CustObj` class.

You can use the CAST function to cast an object reference to a subclass and invoke a method defined in that subclass using the following syntax:

**Syntax**

```
method-name( INPUT CAST( object-reference, subclass-name ), ... ).
```

You can also use this syntax to invoke a method on a class that implements the referenced interface from which you cast the specified class.

**See also** DYNAMIC-CAST function, Type-name syntax, USING statement

### CATCH statement

Defines an error-handling **end block** for any undoable ABL block. An end block is an ABL block that can occur only within another block. The block containing the end block is known as the **associated block**. End-blocks must occur between the last line of executable code in the associated block and the END statement.

The CATCH end block executes when an error raised in the associated block is compatible with the error type specified in the CATCH block. To be compatible, the error type must be the error type specified in the CATCH statement, or it must be a sub-type (sub-class) of the specified type. CATCH blocks take precedence over any implicit or explicit ON ERROR directives for the associated block. This is the syntax for the CATCH statement and its related blocks:
CATCH statement

Syntax

```
block-statements

CATCH error-variable AS class error-class:

catch-logic

END [ CATCH ] .

[ block-end-statement ]
```

**block-statements**

All of the statements of an enclosing associated ABL block, except for its **block-end-statement**. The enclosing associated block can be any ABL block, including another CATCH block.

**error-variable**

The variable name that references the error object generated by the error condition. Typically, you do not define the **error-variable** ahead of time with the DEFINE VARIABLE statement. The AVM recognizes a new variable name on the CATCH statement as a new **error-variable** definition. Each CATCH in an associated block must have a unique **error-variable**. You can reuse an **error-variable** name in a different associated block, as long as its type is compatible with the new definition.

```
[ CLASS ] error-class
```

Typically Progress.Lang.SysError for system errors or Progress.Lang.AppError (or your subclass) for application errors. Optionally, you can provide the CLASS keyword.

**catch-logic**

All statements allowed in a CATCH block, which can include any valid ABL statement except an input blocking statement. For more information on CATCH block execution, see the notes for this reference entry.

**block-end-statement**

For all associated ABL blocks except a main external procedure block, the END statement terminating the enclosing associated block of the CATCH block. External procedure blocks have no terminating END statement.

**Examples**

The following code fragment shows CATCH blocks for associated DO blocks:
In the following example, the CATCH block will catch any ABL system error:

```abl
DO ON ERROR UNDO, LEAVE:
  FIND FIRST Customer NO-LOCK WHERE Customer.CustNum = 5000.

  CATCH oneError AS Progress.Lang.SysError:
    MESSAGE oneError:GetMessage(1) VIEW-AS ALERT-BOX BUTTONS OK.
    END CATCH.

  CATCH twoError AS Progress.Lang.ProError:
    MESSAGE twoError:GetMessage(1) VIEW-AS ALERT-BOX BUTTONS OK.
    END CATCH.
  END CATCH.

END. /* FIRST DO */

DO ON ERROR UNDO, LEAVE:
  FIND FIRST Customer NO-LOCK WHERE Customer.CustNum = 6000.

  /* You can reuse an error-variable from a different associated block */
  CATCH oneError AS Progress.Lang.SysError:
    MESSAGE oneError:GetMessage(1) VIEW-AS ALERT-BOX BUTTONS OK.
    END CATCH.

  /* NOT LEGAL: Each CATCH block in an associated block must have a unique
   error-variable. */
  CATCH oneError AS Progress.Lang.ProError:
    MESSAGE oneError:GetMessage(1) VIEW-AS ALERT-BOX BUTTONS OK.
    END CATCH.
  END CATCH.

END. /* SECOND DO */
```

In the following example, the CATCH block will catch any ABL system error:

```abl
DEFINE VARIABLE iCust AS INTEGER NO-UNDO INITIAL 5000.

FIND Customer NO-LOCK WHERE Customer.CustNum = iCust. /* Will fail */

  /* Won't execute because FIND fails */
  MESSAGE "Customer found" VIEW-AS ALERT-BOX BUTTONS OK.

  /* The associated block for this CATCH block is the main block of the .p */
  CATCH eSysError AS Progress.Lang.SysError:
    MESSAGE eSysError:GetMessage(1) VIEW-AS ALERT-BOX BUTTONS OK.
    END CATCH.
```

**Notes**

- One or more CATCH blocks are positioned at the end of the associated block. If a FINALLY end block is also used, the CATCH blocks comes before the FINALLY block. The syntax for an associated block using end blocks is as follows:
Note that a CATCH block can also contain a CATCH or FINALLY block, just as a FINALLY block can contain a CATCH or FINALLY block. For more information on FINALLY blocks, see the FINALLY statement reference entry.

Thus, the following blocks can have a CATCH block:

- CATCH block (recursive)
- DO (if configured with TRANSACTION or ON ERROR, UNDO)
- FOR
- REPEAT
- Main (.p procedure file)
- Internal procedures
- User-defined functions
- Methods
- Property accessors
- Constructors
- Destructors
- ON
- CATCH
- FINALLY

- ABL issues a compile-time error if a CATCH end block is present in a simple DO block, since simple DO blocks do not have error handling capabilities. DO blocks must have either TRANSACTION or an ON ERROR directive in order to have a CATCH. For example:
• The code within a CATCH block is only executed if an ERROR of type `error-class` (or a sub-type) is raised within the body of the associated block. This behavior is also true if any sub-routine called by the associated block returns or raises an error of type `error-class`. When ERROR is raised, if there is an active transaction, the associated block is undone before the AVM begins executing the statements within the CATCH block.

• An associated block may have multiple CATCH blocks, each of which handles a different error class. If an error type satisfies multiple CATCH statements, the AVM will execute the code in the first CATCH block that matches the error type. It will not execute multiple CATCH blocks. Therefore, if multiple CATCH blocks are specified, the CATCH block for the more specialized error classes should come first, as shown:

```abl
FOR EACH Customer:
   /* Code body of the associated block */
   /* This CATCH specifies the most specialized user-defined error class. It will catch only myAppError error objects or objects derived from myAppError. */
   CATCH eMyAppError AS Acme.Error.myAppError:
      /* Handler code for Acme.Error.myAppError condition. */
      END CATCH.
   /* This CATCH will handle Progress.Lang.AppError or any user-defined application error type, except for eMyAppError which would be handled by the preceding CATCH block. */
   CATCH eAppError AS Progress.Lang.AppError:
      /* Handler code for AppError condition. */
      END CATCH.
   /* This CATCH will handle any error raised by an ABL statement. Since it inherits from the same object as AppError in the class hierarchy, this CATCH could come before or after the CATCH for AppError */
   CATCH eSysError AS Progress.Lang.SysError:
      /* Handler code for SysError condition. */
      END CATCH.
   /* This will catch any possible error raised in the ABL. */
   CATCH eError AS Progress.Lang.Error:
      /* Handler code for any error condition. */
      END CATCH.
END. /* FOR EACH Customer, associate block */
```

• The compiler will issue a warning message if a block contains a CATCH block that is not reachable. For example, the following code will cause the compiler to issue a warning, since the CATCH of `myAppError` can never be executed:

```abl
DO TRANSACTION
   . . .
   CATCH . . . :
   . . .
   END CATCH.
END.
```
• It is valid to have both an explicit ON ERROR directive and a CATCH on the same associated block. You might want to CATCH certain error types and handle them directly, and have all other error types handled by the ON ERROR directive of the associated block.

If error is raised in a block and is not handled by a CATCH block, then the error is handled by the ON ERROR directive of the associated block. This could be an explicit ON ERROR phrase, or the implicit (default) ON ERROR directive for the block type.

• A CATCH block can have a CATCH block within it. In this case, the contained CATCH block only handles errors raised within the CATCH block. To prevent infinite looping, any UNDO, THROW statement within the top-level CATCH block or any CATCH block nested within it immediately throws the error to the block that contains the associated block of the top-level CATCH block. For example:

```plaintext
FOR EACH Customer:
/* FOR EACH code body */

DO ON ERROR UNDO, LEAVE:
/* DO code body */
CATCH eAppError AS Progress.Lang.AppError:
/* CATCH code body */
CATCH eSysError AS Progress.Lang.SysError:

/* Will be handled by CATCH anyError... */
END CATCH.
END CATCH.
END. /* FOR EACH code body */
```

• The CATCH block is an end block of its associated block. A CATCH block can only execute after the execution (or each iteration) of the associated block. The CATCH block only executes when error is raised in the associated block and the CATCH error type is compatible with the type of the raised error. Any transaction within the associated block will be undone and records will be released before the CATCH block executes.

• The CATCH block is an undoable block with implicit ON ERROR UNDO, THROW error handling. You cannot explicitly override the ON ERROR directive for a CATCH block. If a statement within the CATCH block raises ERROR and there is no nested CATCH
block, the CATCH block will be undone, and the ERROR will be raised in the block that encloses the associated block of the CATCH. So a statement that raises ERROR within a CATCH end block causes the following to occur:

a) UNDO the CATCH block.

b) Leave the CATCH and its associated block.

c) THROW the error to the enclosing block. If the catch block is at the routine level, then the error gets thrown to the caller of the routine.

The same behavior occurs for an explicit UNDO, THROW statement in a CATCH block. For example:

```progress
DO ON ERROR UNDO, LEAVE:
	/* Check for Orders */
	/* Fails and throws Progress.Lang.SysError. Execution goes to CATCH */
	FIND FIRST Order NO-LOCK WHERE Order.CustNum = 1000.
	MESSAGE "Order found". /* MESSAGE does not execute */

	CATCH eSysError AS Progress.Lang.SysError:
		/* Check if Customer exists, which fails. ON ERROR UNDO, THROW for CATCH will raise ERROR in main block of .p - execution goes to CATCH in main block */
		FIND FIRST Customer NO-LOCK WHERE Customer.CustNum = 1000.
	END CATCH.
END.

MESSAGE "Customer found". /* MESSAGE does not execute */

/* This CATCH is for the main block of the .p */
CATCH eSysError AS Progress.Lang.SysError:
	MESSAGE eSysError:GetMessage(1) VIEW-AS ALERT-BOX BUTTONS OK.
END CATCH.
```

- If there is a FINALLY block in the associated block, the FINALLY code will be executed before ERROR gets raised in the block enclosing the associated block.

- The scope of buffers referenced in a CATCH block is the smallest enclosing block outside of the associated block that encompasses all references to the buffer.

In this example, DO TRANSACTION and CATCH both reference the Customer buffer:
As the result of the reference to the Customer buffer in the CATCH block in the previous example, the scope of the Customer buffer is raised to the procedure level (myproc.p), since the smallest enclosing block of the DO TRANSACTION is the procedure block.

- The code in any CATCH block can contain an explicit flow-of-control directive, meaning LEAVE, NEXT, RETRY, RETURN, or THROW. (RETRY and THROW require UNDO.) Since CATCH is an undoable block, LEAVE, NEXT, and RETRY without a label will apply to the CATCH block itself and not the associated block.

If you want LEAVE, NEXT, or RETRY to apply to the associated block of a CATCH block, you must use the existing label syntax for these statements.

An explicit UNDO, THROW in a CATCH block causes the AVM to raise ERROR in the block that encloses the associated block of the CATCH block; not the associated block itself.

In this example, LEAVE in the CATCH applies to the CATCH:
In this example, the procedure gives the user three chances to get the right order number:

```sql
DEFINE VARIABLE iOrdNum AS INTEGER NO-UNDO.
DEFINE VARIABLE iTries AS INTEGER NO-UNDO INITIAL 1.

blk1:
FOR EACH Customer NO-LOCK:
    UPDATE iOrdNum.
    FIND Order NO-LOCK WHERE Order.CustNum = Customer.CustNum
        AND Order.OrderNum = iOrdNum. /* Can Fail and raise ERROR */
    ... 
    CATCH eSysError AS Progress.Lang.SysError:
        MESSAGE "Order " iOrdNum " does not exist for Customer ".
        IF iTries <= 3 THEN
            iTries = iTries + 1.
        ELSE DO:
            MESSAGE "Too many tries for this Customer".
            iTries = 1.
            /* Leave the CATCH. Execution will resume with the next 
                iteration of the FOR EACH */
            UNDO, LEAVE blk1.
        END.
    END CATCH.
END. /* FOR EACH Customer */
```

In this example, LEAVE the FOR EACH in the occurrence of a PrinterDown application error:

```sql
DEFINE VARIABLE iOrdNum AS INTEGER NO-UNDO.
DEFINE VARIABLE lSomeCondition AS LOGICAL NO-UNDO.

FOR EACH Customer:
    UPDATE iOrdNum.
    FIND Order NO-LOCK WHERE Order.CustNum = Customer.CustNum
        AND Order.OrderNum = iOrdNum. /* Can Fail and raise ERROR */
    /* Won't get here if FIND fails */
    DISPLAY Order.OrderNum Order.ShipDate.

    CATCH eSysError AS Progress.Lang.SysError:
        MESSAGE "Order " iOrdNum " does not exist for Customer ".
        IF lSomeCondition THEN
            UNDO, LEAVE.
        /* More statements in the CATCH that will execute if UNDO, LEAVE 
            didn't execute */
        END CATCH.
END. /* FOR EACH Customer */
```
If there is no explicit flow-of-control statement in the CATCH block, the AVM will leave the CATCH block and execute the default error action for the associated block after executing the last statement in the CATCH block and any code within a FINALLY block. This means RETRY for all blocks. When no input blocking statements are present, the AVM prevents infinite looping by changing the RETRY to NEXT for iterating blocks or LEAVE for non-iterating blocks.

Note: For more information on infinite loop protection in error handling, see OpenEdge Getting Started: ABL Essentials.

In the following code, if an Acme.Error.myAppError is caught the explicit UNDO, THROW statement causes the caught error to be thrown to the block enclosing the FOR EACH (remember that UNDO, THROW in a CATCH means leave associated block, then throw). However, if a Progress.Lang.SysError is caught the AVM will execute a NEXT on the FOR EACH block. For example:

```abl
DEFINE VARIABLE iOrdNum AS INTEGER NO-UNDO.
DEFINE VARIABLE iTries AS INTEGER NO-UNDO INITIAL 1.

blk1:
FOR EACH Customer NO-LOCK:
    UPDATE iOrdNum.

    /* Can Fail and raise ERROR - execution will go to CATCH for
     * Progress.Lang.SysError */
    FIND Order NO-LOCK WHERE Order.CustNum = Customer.CustNum
        AND Order.OrderNum = iOrdNum.

    /* Successfully found Order. Try to print invoice. If PrintInvoice.p
     * throws an Acme.Error.PrinterDownError error, just leave the FOR EACH
     * block. If PrintInvoice.p throws any other type of AppError, try with
     * the next customer. */
    RUN PrintInvoice.p (INPUT Order.OrderNum).
...

CATCH pde AS Acme.Error.PrinterDownError:
    MESSAGE "Printer down...aborting".
    UNDO, LEAVE blk1.
END CATCH.

CATCH eAppError AS Progress.Lang.AppError:
    MESSAGE "Problem printing invoice for order " iOrdNum.
    /* Leave the CATCH. Execution will resume with the next iteration of
     * the FOR EACH */
    UNDO, NEXT blk1
END CATCH.
END. /* FOR EACH Customer */
```
The presence of a CATCH in an undoable block causes the AVM to suppress Progress system error messages for all statements within the block, in the same way that NO-ERROR works on individual statements. If there is a CATCH on Progress.Lang.SysError, the message(s) will be added to the Progress.Lang.SysError object that is available in the CATCH. If there is no CATCH on Progress.Lang.SysError, and the Progress.Lang.SysError is not re-thrown (by way of ON ERROR UNDO, THROW on the block), the error messages from the Progress.Lang.SysError will be written to the current output destination and the AVM will execute the ON ERROR directive for the block.

In this example, a CATCH handles the error and the error message is suppressed:

```plaintext
DEFINE VARIABLE myInt as INTEGER NO-UNDO INITIAL 5.
DO ON ERROR UNDO, LEAVE:
/* Raises ERROR and throws Progress.Lang.SysError. Error message suppressed and execution goes to CATCH */
  FIND Customer 1000.
  MESSAGE "After Find". /* Will not get here */
CATCH eSysError AS Progress.Lang.SysError:
  /* Will display "** Customer record not on file. (138)" */
  MESSAGE eSysError:GetMessage(1) VIEW-AS ALERT-BOX.
  /* Leave the CATCH, then the DO block */
END CATCH.
END.
```

In this example, there is no CATCH block that handles the error and the error message is not suppressed:

```plaintext
FOR EACH Customer ON ERROR UNDO, LEAVE:
  /* FOR EACH code */
  CATCH eSysError AS Progress.Lang.SysError:
    /* Handler code for SysError condition */
    /* RETRY on FOR EACH after leaving the CATCH, which becomes LEAVE if there are no I/O statements. */
  END CATCH.
  CATCH myAppErr AS Acme.Error.myAppError:
    /* Handler code for myAppError condition */
    /* THROW error to block enclosing the FOR EACH */
    UNDO, THROW myAppErr.
  END CATCH.
END.
```
CHOOSE statement

After you display data, the CHOOSE statement moves a highlight bar among a series of choices and selects a choice when you press GO, RETURN, or enter a unique combination of initial characters.

This statement is supported only for backward compatibility.

Note: Does not apply to SpeedScript programming.

Syntax

```
CHOOSE
{  { ROW field [ HELP char-constant ] }  
    | { FIELD { field [ HELP char-constant ] } ... }  
}  
[ AUTO-RETURN ] [ COLOR color-phrase ] 
[ GO-ON ( key-label ... ) ] [ KEYs char-variable ] 
[ NO-ERROR ] [ PAUSE expression ] 
{ [ frame-phrase ] }
```

You can specify the AUTO-RETURN, COLOR, GO-ON, KEYS, NO-ERROR, and PAUSE options in any order.

ROW field

Tells CHOOSE to move a highlight bar among iterations of a down frame. The field is the name of the field that you want the highlight bar to begin highlighting. The ROW option is useful for browsing through a set of records, although field does not have to refer to database records.

If you use the ROW option with the CHOOSE statement, use the SCROLL statement as well. See the SCROLL statement reference entry examples.

If you use ROW, you can add a COLOR statement to control the video display highlighting.

See also

ON ERROR phrase, RETURN statement, ROUTINE-LEVEL ON ERROR UNDO, THROW statement, UNDO statement
FIELD field

Tells CHOOSE to move a highlight bar through a set of fields or set of array elements in a frame. The field argument is the table record or array variable with fields or elements through which you want to move the highlight bar. These fields or array elements must be defined as ABL default FILL-IN widgets (not specified with the FILL-IN NATIVE option). The FIELD option is useful for building menus. You can also supply help for field.

HELP char-constant

Lets you provide help text for each field in a CHOOSE FIELD statement or for the entire CHOOSE ROW statement. For the CHOOSE ROW statement, the help text is displayed throughout the CHOOSE operation. For the CHOOSE FIELD statement, the help text you specify for a field is displayed whenever you move to the field.

AUTO-RETURN

Tells the AVM to use the selection when you enter a unique string of initial characters. When you use AUTO-RETURN and the user enters a unique string of initial characters, the AVM sets the value of LASTKEY to KEYCODE (return).

COLOR color-phrase

Specifies a video attribute or color for the highlight bar. Following is the syntax for color-phrase:

Syntax

```
{ NORMAL
  | INPUT
  | MESSAGES
  | protermcap-attribute
  | dos-hex-attribute
  | { [ BINK- ] [ BRIGHT- ]
    [ fgnd-color ] [ bgnd-color ] }
  | { [ BINK- ] [ RVV- ] [ UNDERLINE- ] [ BRIGHT- ]
    [ fgnd-color ] }
  | VALUE ( expression )
}
```

For more information on color-phrase, see the COLOR phrase reference entry.

GO-ON ( key-label ) . . .

Names key-labels for keys that cause CHOOSE to return control to the procedure. If you do not use the GO-ON option, CHOOSE returns control to the procedure when the user presses GO, RETURN, END-ERROR, or types a unique substring when AUTO-RETURN is in effect. If you don’t specify F1, RETURN, or F4, those keys are still GO-ON keys by default.

KEYS char-variable

If you want to highlight a particular choice when entering a CHOOSE statement, or if you want to know what keys the user pressed to make a selection, use the KEYS option. When
you use the KEYS option, you must give the name of a character variable, char-variable. If char-variable is initialized to one of the choices before entering the CHOOSE statement, the AVM highlights that choice. As the user presses keys to move the highlight bar, the AVM saves those keystrokes in char-variable. You can test the value of char-variable after the CHOOSE statement returns control to the procedure. There is a 40-character limit when using the KEYS option.

**NO-ERROR**

Overrides default error handling by the CHOOSE statement, and returns control to the procedure. If you do not use the NO-ERROR option, the CHOOSE statement causes the terminal to beep when the user presses an invalid key.

If you use the NO-ERROR option and the user presses an invalid key, the CHOOSE statement ends. At this point, you usually want to use the LASTKEY function to test the value of the last key the user pressed and then take the appropriate action.

Note that the NO-ERROR option of the CHOOSE statement does not have any affect on the ERROR-STATUS system handle.

**PAUSE expression**

Specifies a time-out period in seconds. If the user does not make a keystroke for the specified number of seconds, the CHOOSE statement times out and returns control to the procedure. The time-out period begins before the user’s first keystroke and is reset after each keystroke. If CHOOSE times out, the value of LASTKEY is -1. Use time-out period to prevent inactivity.

**frame-phrase**

Specifies the overall layout and processing properties of a frame. For more information on frame-phrase, see the Frame phrase reference entry.

If your procedure might eventually run on a spacetaking terminal, use the ATTR-SPACE option for the CHOOSE statement. Omitting this option makes the highlight bar invisible.

**Example**

The following procedure displays a strip menu with four choices. The procedure defines two arrays; one holds the items for selection on the menu, the other holds the names of the programs associated with the menu selections. The CHOOSE statement allows the user to select an item from the strip menu. The AVM finds the number (within the array) associated with the item selected and the program associated with that number in the proglist array. The AVM runs the program, if it exists, and displays a message. It also allows the user to select another item if the program does not exist. (In your own application, you associate actions with items selected by the CHOOSE statement.)
The GO-ON option sets the GET key to perform an action like GO. With the LASTKEY function, you could check for F5 and take another action relevant to your application.

**Notes**

- If you do not specify help text in the CHOOSE statement, any help text you specify for the field in the Data Dictionary is displayed instead. If no help text is specified in either the CHOOSE statement or Data Dictionary, then the status default message is displayed throughout the CHOOSE statement.

- The CHOOSE statement takes different actions depending on the key you press and whether you use the NO-ERROR option, as shown in Table 11.

---

**Table 11: CHOOSE statement actions**

<table>
<thead>
<tr>
<th>Key</th>
<th>NO-ERROR</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>Valid cursor motion¹</td>
<td>N/A</td>
<td>Clear saved keys and move highlight bar.</td>
</tr>
<tr>
<td>Invalid cursor motion²</td>
<td>NO</td>
<td>Clear saved keys and beep terminal.</td>
</tr>
<tr>
<td>Invalid cursor motion²</td>
<td>YES</td>
<td>Clear saved keys and return control to procedure.</td>
</tr>
<tr>
<td>A non-unique string followed by an alphanumeric character that does not form a matchable string³</td>
<td>NO</td>
<td>Clear saved keys and try to match the last key entered. If no match is available then beep terminal.</td>
</tr>
</tbody>
</table>
Once you run this procedure, your window looks like the following:

### Table 11: CHOOSE statement actions

<table>
<thead>
<tr>
<th>Key</th>
<th>NO-ERROR</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>A non-unique string followed by an alphanumeric character that does not form a matchable string with the other characters</td>
<td>YES</td>
<td>Return control to procedure.</td>
</tr>
<tr>
<td>An invalid string</td>
<td>NO</td>
<td>Beep terminal.</td>
</tr>
<tr>
<td>An invalid string</td>
<td>YES</td>
<td>Return control to the procedure and, if the KEYS option was used, save any printable keys.</td>
</tr>
<tr>
<td>Other keys(^4)</td>
<td>NO</td>
<td>Beep terminal.</td>
</tr>
<tr>
<td>Other keys(^4)</td>
<td>YES</td>
<td>Return control to procedure.</td>
</tr>
</tbody>
</table>

1. Valid cursor motion keys within a frame are CURSOR UP, CURSOR DOWN, CURSOR RIGHT, CURSOR LEFT, SPACEBAR, TAB, and BACKTAB.
2. Invalid cursor motion keys are CURSOR UP, CURSOR DOWN, CURSOR RIGHT, and CURSOR LEFT that cause the cursor to move outside the frame.
3. The `r-chs1.p` procedure below, shows what the CHOOSE statement does when the user enters a non-unique string followed by a character that, together with the rest of the string, does not match anything.
4. Other keys are non-cursor-motion, non-alphanumeric keys (function keys, BACKSPACE) except for: HELP, STOP, RETURN, GO, END, ERROR, END-ERROR. Keys defined to do the actions of these keys still do so.

#### r-chs1.p

```plaintext
DEFINE VARIABLE abc AS CHARACTER NO-UNDO FORMAT "x(3)" EXTENT 42.
DEFINE VARIABLE ix  AS INTEGER NO-UNDO.

DO ix = 1 TO 42:
   abc[ix] = STRING(ix, ">9").
END.

DISPLAY abc NO-LABELS WITH ATTR-SPACE CENTERED ROW 4
   TITLE " CHOOSE STATEMENT " FRAME f-choose WIDTH 36.
DISPLAY "Enter your selection " WITH CENTERED NO-BOX
   FRAME f-instruct.
PAUSE 1 BEFORE-HIDE NO-MESSAGE.
REPEAT:
   HIDE MESSAGE.
   CHOOSE FIELD abc AUTO-RETURN WITH FRAME f-choose.
   MESSAGE "You selected -> " FRAME-VALUE.
END.
```

Once you run this procedure, your window looks like the following:
• When you press 2, CHOOSE moves the highlight bar to 2. When you press 4, CHOOSE moves the bar to 24. When you press 6, CHOOSE looks for the string 246. Because it cannot find the string, it matches the last key pressed (6) and places the highlight bar on 6.

• A choose field can temporarily become a handle type for internal purposes, but is not actually a widget since it does not have its own set of attributes and widgets. Therefore, you might see myhandle:TYPE = choose field in the widget tree, but you cannot manipulate the choose field.

See also  COLOR phrase, Frame phrase, SCROLL statement, STATUS statement

CHR function

Converts an integer value to its corresponding character value.

Syntax

```plaintext
CHR ( expression [ , target-codepage [ , source-codepage ] ] )
```

- **expression**

  An expression that yields an integer value that you want to convert to a character value.

  If the value of `expression` is in the range of 1 to 255, CHR returns a single character. This character might not be printable or might not display on certain terminals. For a value greater than 255 and less than 65535, the CHR function checks for a corresponding lead-byte value. If the integer value corresponds to a valid lead-byte, the CHR returns a double-byte character.

  The CHR function returns a null string if the `expression` yields a value outside of the range 1 to 65534 or the `expression` yields a value in the range 256 to 65534 and the value does not correspond to a valid lead-byte.

- **target-codepage**

  A character-string expression that evaluates to the name of a code page. The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management). If you supply a
non-valid name, the CHR function returns a null string. Before returning a character value, the CHR function converts expression from source-codepage to target-codepage. The returned character value is relative to target-codepage. If you do not specify target-codepage, no code page conversions occur.

source-codepage

A character-string expression that evaluates to the name of a code page. The name that you specify must be a valid code page name available in the DLC/convmap.cp file. If you supply a non-valid name, the CHR function returns a null string. The source-codepage specifies the name of the code page to which expression is relative. The default value of source-codepage is the value of SESSION:CHARSET.

Example

The r-chr.p procedure initializes the 26 elements of the letter array to the letters A through Z.

```
r-chr.p
```

```r
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE letter AS CHARACTER NO-UNDO FORMAT "X(1)" EXTENT 26.
DO ix = 1 TO 26:
    letter[ix] = CHR((ASC("A")) - 1 + ix).
END.
DISPLAY SKIP(1) letter WITH 2 COLUMNS NO-LABELS
    TITLE "T H E  A L P H A B E T".
```

Notes

- The CHR function returns the corresponding character in the specified code page. By default, the value of SESSION:CHARSET is iso8859-1. You can set a different internal code page by specifying the Internal Code Page (-cpinternal) parameter. For more information, see OpenEdge Deployment: Startup Command and Parameter Reference.
- The CHR function is double-byte enabled. For a value greater than 255 and less than 65535, it checks for a lead-byte value. If the lead-byte value is valid, the AVM creates and returns a double-byte character.

See also

ASC function, CODEPAGE-CONVERT function, SESSION system handle, STRING function

Class-based data member access

References a data member of a class in order to read or write its value.

Syntax

```
```

class-type-name

The name of an ABL or .NET class type that defines the specified data member as a static member. The use of class-type-name to access a static data member is optional when you access the data member from within the class hierarchy where it is defined. For more information, see the notes for this reference entry. You can use class-type-name only to access data members that can be defined as PUBLIC. For more information, see the notes for this reference entry. You cannot use class-type-name to access an instance data
member. For more information on specifying class (object) type names, see the Type-name syntax reference entry. You also can use the unqualified class name with the presence of an appropriate USING statement.

**object-reference**

Specifies a reference to an instance of an ABL or .NET class (an object) that defines the specified data member as an instance member. The use of **object-reference** to access an instance data member is optional when you access the data member from within the class hierarchy where it is defined. For more information, see the notes for this reference entry. For more information, see the notes for this reference entry. You cannot use **object-reference** to access a static data member. For information on specifying object references, see the reference entry for a Class-based object reference.

**data-member-name**

The name of a data member you want to access. In .NET, a data member is referred to as a field. A data member is a data element that is defined in, and at, the level of a class definition (as distinct from a local data element that is defined in and at the level of a method definition). If it is an instance data member, a separate copy exists for each instance of its defining class, for as long as the class instance exists. If it is a static data member, only one copy exists for the defining class type for the entire ABL session, regardless if any instance of the class exists. A data member is available either inside or outside of the class hierarchy depending on its access mode.

**[ index ]**

Specifies the index to reference an element of an ABL array data member, where **index** is an integer value that identifies the element. The brackets are a required part of the index syntax.

**Note:** To access the elements of a .NET array object, you must use the .NET SetValue( ) and GetValue( ) methods on the array object instead. For more information on using these methods, see the Microsoft .NET Framework documentation and the Parameter passing syntax reference entry in this manual.

**Examples**

The following code fragment shows a reference to a public instance data member (**hHighCustData**) on an instance of the sample class, **r-CustObj:**

```
DEFINE VARIABLE rObj AS CLASS r-CustObj NO-UNDO.
rObj = NEW r-CustObj( ) NO-ERROR.
MESSAGE "Number of buffers =" rObj:hHighCustData:NUM-BUFFERS VIEW-AS ALERT-BOX.
```

This instance data member is a handle to a ProDataSet that is used, in this case, to reference the NUM-BUFFERS attribute, which returns the number of buffers in the ProDataSet.

The following code fragment shows a reference to a public static data member (**hHighCustData**) on the sample class type, **r-CustObjStatic:**
This static data member is also a handle to a similar ProDataSet, and example code performs the same function as the previous instance code without having to instantiate a class.

For more information on these data members and the sample classes in which they are defined, see the examples in the CLASS statement reference entry.

**Notes**

- Using the appropriate syntax, you can read and write data as defined for the data member type. For more information on the supported ABL data member types, see the reference entry for the CLASS statement and the DEFINE statement for each type of data member.

- You can also read or write a .NET data member, depending on its definition. For example, if a given .NET data member is defined as a constant, you can only read the defined value of that data member, but you cannot write to it. .NET data members can also be defined with a variable value as read-only. For information on the definition of a .NET data member, see its field entry in Microsoft .NET, Infragistics, or another third-party class library that defines it. For information on how .NET data types map to ABL data types, see the Data types reference entry.

- If the data member is defined as static, you can access the data member using static type-name syntax whether or not an instance of its defining class exists.

- ABL implicitly defines the default buffers of any database tables you reference within a class definition as private instance data members of the class.

- If you reference an available data member within a static constructor, static method, static property accessor, or as part of another static data member definition that is defined in the same class or class hierarchy as the referenced member (such as referencing a buffer in a static data-source definition), the referenced data member must also be defined as static; attempting to directly reference an instance data member that is defined in the same class or class hierarchy as the referencing static member raises a compile-time error. To reference a buffer for a database table in a static data member definition, you must define and reference an alternate static buffer data member for the table with a compatible access mode.

- If a data member definition includes a reference to another data member defined in the same class, the access mode of the referenced data member must be no less restrictive than the access mode of the data member definition where it is referenced. For example, if a data-source is defined with a PROTECTED access mode, any buffer that it references must be defined as either PROTECTED or PUBLIC.

- You cannot use a class instance that is not equal to the THIS-OBJECT system reference to access a private or protected instance data member that is defined in the same class, even though this data member is defined in the instantiating class definition. In ABL, all private and protected data members are instance based and available only to members of a given instance of the class, including (for static data members) the "static instance" in the ABL session.

- From within an ABL class definition, you can reference any data member that is both defined and available within the class hierarchy using its *data-member-name* without a qualifying *object-reference* (for instance, data members) or *class-type-name* (for
static data members). Data members that you can reference directly by \texttt{data-member-name} within the class hierarchy where they are defined include:

- Available variables (and their associated visual widgets) that have a PRIVATE, PROTECTED, or PUBLIC access mode. You can use the \texttt{THIS-OBJECT} system reference as an \texttt{object-reference} to access any available instance variable data member that is defined within the class hierarchy. However, you \textbf{must} use \texttt{THIS-OBJECT} to access any instance variable data member whose name is a reserved keyword. You can also use \texttt{class-type-name} to access any available static variable data member that is defined within the class hierarchy. However, you \textbf{must} use \texttt{class-type-name} to access any static variable data member whose name is a reserved keyword.

- Available buffers, ProDataSets, data sources, queries, and temp-tables that have a PRIVATE or PROTECTED access mode.

- Streams, work-tables, and widgets, including browses, buttons, frames, images, menus, sub-menus, and rectangles that you define in a class block are not data members. Like triggers, these are class-scoped resources that are privately available for use with both instance and static members within the defining class.

- From within a class hierarchy where static data members are defined, you can use a qualifying \texttt{class-type-name} to access only the static variable data members from both ABL and .NET, including the elements of arrays. To access all other static data members (such as temp-tables or buffers) defined in the current class hierarchy, you must only use an unqualified \texttt{data-member-name}.

- From outside a class hierarchy, you must reference any available instance data member using its \texttt{data-member-name} qualified by an \texttt{object-reference} to the class instance where the data member is defined, and you must reference any available static data member using the \texttt{class-type-name} of the class where the data member is defined as static. The only data members that are available outside the class hierarchy where they are defined are variables defined as PUBLIC (and any associated visual widgets for instance variables), including the elements of arrays.

\textbf{Note:} From outside the class hierarchy where they are defined, you cannot apply events (using the APPLY statement) to triggers defined for widgets associated with PUBLIC data members.

\textbf{See also} \quad \texttt{Class-based object reference, CLASS statement, Type-name syntax}

\textbf{Class-based method call}

Invokes a method of a class. If the method returns a value, the method call can appear anywhere that an expression can appear, and it can also appear as a single statement, ignoring the return value. If the method is VOID (does not return a value), the method call must appear as a single statement.
Class-based method call

Syntax

```
[ { class-type-name | object-reference } : ]
method-name ( [ parameter [, parameter ] ... ] ) [ NO-ERROR ]
```

class-type-name

The name of an ABL or .NET class type that defines the specified method as a static member. The use of class-type-name to call a static method is optional when you call the method from within the class hierarchy where it is defined. For more information, see the notes for this reference entry. You cannot use class-type-name to call an instance method. For more information on specifying class (object) type names, see the Type-name syntax reference entry. You can use the unqualified class name with the presence of an appropriate USING statement.

object-reference

Specifies a reference to an ABL or .NET class instance (an object) that defines the specified method as an instance member. The use of object-reference to call an instance method is optional when you call the method from within the class hierarchy where it is defined. For more information, see the notes for this reference entry. You cannot use object-reference to call a static method. For information on specifying object references, see the reference entry for a Class-based object reference.

method-name

Specifies the name of an ABL or .NET class method you want to call. A class method is a named block of ABL or .NET code, similar to a procedure or user-defined function, that is defined in a class. An instance method is available for an instance of the class for as long as the class instance exists. A static method is available for the defining class type during the entire ABL session, regardless if an instance of the class exists. A class method is available inside or outside of the class hierarchy depending on its access mode.

```
( [ parameter [, parameter ] ... ] )
```

Specifies zero or more parameters passed to the method. You must provide the parameters identified by the specified method, matched with respect to number, data type, and mode. To invoke a method that is overloaded in the class, you must specify sufficient information for each parameter in order to disambiguate methods that have similar parameter lists. Otherwise, the AVM raises an error identifying the ambiguity.

For more information on parameter passing syntax and on disambiguating overloaded ABL and .NET methods, see the Parameter passing syntax reference entry.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:
• Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

• Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

• Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

• NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

• A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

• When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

• If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

• To access more comprehensive error information for a .NET exception, use a CATCH end block instead of the NO-ERROR option. For more information on handling .NET exceptions, see the sections on .NET error handling in OpenEdge Development: GUI for .NET Programming.

**Examples**
The following code fragment shows a call to a public instance method (SetHighCustomerData( )) on an instance of the sample class, r-CustObj:
Class-based method call

This instance method initializes instance data for the class.

The following code fragment shows a call to a public static method (SetHighCustomerData( )) on the sample class type, r-CustObjStatic:

```
DEFINE VARIABLE rObj AS CLASS r-CustObj NO-UNDO.
rObj = NEW r-CustObj( ) NO-ERROR.
rObj: SetHighCustomerData( ) NO-ERROR.
```

This static method initializes class static data without having to instantiate the class, as in the previous instance code.

For more information on these methods and the sample classes in which they are defined, see the examples in the CLASS statement reference entry.

**Notes**

- Using the appropriate syntax, you can invoke the method as a statement (without returning a value) or invoke the method in an expression that uses the defined return value according to its data type. For information on ABL methods and their definition, see the METHOD statement reference entry. For information on the definition of a .NET method, see its entry in the Microsoft .NET, Infragistics, or other class library that defines it. For information on how .NET data types map to ABL data types, see the Data types reference entry.

- If the method is defined as static, you can call the method whether or not an instance of its defining class exists.

- If you reference an available method within a static constructor, static method, or static property accessor that is defined in the same class or class hierarchy as the referenced method, the referenced method must also be defined as static; attempting to directly reference an instance method that is defined in the same class or class hierarchy as the referencing static member raises a compile-time error.

- You cannot use a class instance that is not equal to the THIS-OBJECT system reference to call a private or protected instance method that is defined in the same class, even though this method is defined in the instantiating class definition. In ABL, all private and protected methods are instance based and available only to members of a given instance of the class, including (for static methods) the "static instance" in the ABL session.

- From within an ABL class definition, you can typically invoke any instance method that is defined and available within the class hierarchy by referencing its method-name and any parameter list without a qualifying object-reference. However, if the method name is a reserved keyword, you must call the method using THIS-OBJECT as the object-reference. If the instance method is defined as an OVERRIDE method, you can invoke the method implementation that it overrides in the most derived class where it is defined using SUPER as the object-reference. For more information, see the reference entry for the SUPER system reference.

- From within a class definition, you can typically invoke any static method that is defined and available within the class hierarchy by referencing its method-name and any parameter
list without a qualifying `class-type-name`. However, if the method name is a reserved keyword, you must call the method using the qualifying `class-type-name`, even if the method is called from within the class that defines it. If the static method is defined as an OVERRIDE (redefining) method, you can invoke any static method implementation in the class hierarchy that it redefines by using the qualifying `class-type-name` of the class that defines the particular method implementation you want to call.

- From outside a class hierarchy, you can only invoke an available instance method by referencing its `method-name` and its parameters qualified by an `object-reference` to the class instance where the method is defined; you can only invoke an available static method by referencing its `method-name` and its parameters qualified by the `class-type-name` of the class that defines the method as static. The only methods defined within a class hierarchy that are available outside the hierarchy are methods defined as PUBLIC.

- You can call an abstract method either from within the class that defines it or on an `object-reference` defined as the type of the abstract class that defines it. Although an abstract method is defined without an implementation, at run time, the method is always implemented in a derived class. So, any reference to an abstract method is always resolved by the most derived class that implements it.

- ABL has the following limitations on the .NET methods you can call:

  - You cannot call the instance method, `System.Windows.Forms.Form:ShowDialog()`, outside of a WAIT-FOR statement. For more information, see the WAIT-FOR statement (.NET and ABL) reference entry.

  - You cannot call a .NET generic method. Similar to a .NET generic type, a .NET generic method has a name that is appended with a comma-separated list of one or more type parameters enclosed in angle brackets, for example, `Add<T, S>(tVar, sVar)`. In this case, you would substitute .NET data types for the parameters T and S when you called the method. ABL does not currently support any reference to these methods. For more information on ABL support for .NET generic types, see the Data types reference entry.

See also

- Class-based object reference, METHOD statement, Parameter passing syntax, SUPER system reference, THIS-OBJECT system reference, Type-name syntax

Class-based object reference

References an instance of an ABL or .NET class and provides access to PUBLIC or PROTECTED instance class members.
Class-based object reference

Syntax

```
object-reference [ [ key ] ] [ : { data-member
| property
| method
} ]
```

*object-reference*

Specifies a reference to an instance of a class (an object). This can be a variable (data member), property, data member or property array element, handle attribute (such as FIRST-OBJECT), method return value, ABL function return, or user-defined function return value defined for an ABL or .NET object type. It also can be an appropriately-used system reference, such as SUPER or THIS-OBJECT. Its value references an instance of a specified class (class-based object). If it is for a class, the data type of the value can be for the class type itself or for a super class of the referenced class. If it is for an interface, its value can reference an instance of any class that implements that interface.

* [ key ] *

Specifies an indexer for the default indexed property of a .NET class. The brackets are a required part of the syntax.

The *key* value is an index value of any supported .NET data type that identifies the property value you want to reference. If this value is an object reference, you can also use it to access any public instance *data-member*, *property*, or *method* on the .NET class instance that the property references. For more information, see the reference entry for a Class-based property access.

**Note:** ABL also allows you to access the default indexed property of a class by specifying the indexer on the default property name. There is no functional difference between specifying the indexer directly on the object reference and specifying it on the property name. For more information on accessing .NET indexed properties, see the Class-based property access reference entry.

*data-member*

Specifies the name of a PUBLIC instance variable defined in the specified ABL class or of a public instance field defined in the specified .NET class. The value of the ABL variable data member can be written or read for the class instance referenced by *object-reference*. The value of a .NET field can be read or written for the class instance specified by *object-reference*, unless it is defined as a constant (using the C# *const* keyword). If it is a constant, it can only be read. For more information, see the reference entry for a Class-based data member access.

*property*

Specifies the name of a PUBLIC instance property defined in the specified ABL or .NET class. The value of this property can be written or read for the class instance referenced by *object-reference*, depending on the property definition. For more information, see the reference entry for a Class-based property access.
Class-based property access

Specifies the name and any run-time parameters taken by a PUBLIC instance method defined in the specified ABL or .NET class, or a call to a built-in event method. A class method can provide a value, depending on the method definition. For more information on calling class methods, see the reference entry for a Class-based method call. For more information on the built-in event methods, see the “Class Events Reference” section on page 1953.

Notes

- You can obtain an object reference for a .NET object in the same way you can obtain a reference to any ABL class-based object, by creating a new object or obtaining the reference to an existing one. You cannot create or reference instances of the following .NET classes:
  - Classes defined in the .NET default namespace (that is, classes with no namespace defined)
  - System.Threading.Thread or any class derived from it
  - System.Delegate or any delegate type derived from it

- If the documentation for a .NET class includes a member in a list of “Explicit Interface Implementations”, you cannot access that member on an object reference defined as the class type. You can only access that member on an object reference that is defined as (or cast to) a particular interface that defines the method. Thus, ABL documentation refers to such a .NET class member as an explicit interface member.

- You cannot define or otherwise obtain an object reference to a .NET mapped object type (for example, System.Int32), except when overriding a .NET method or when implementing a method or property of a .NET interface. You can only access instances of .NET mapped object types as corresponding ABL primitive types (for example, INTEGER). For more information, see the Data types reference entry. However, you can access .NET static properties and methods on their defining .NET mapped object types.

- ABL classes do not currently support default or indexed properties. So, you cannot reference an ABL class instance using an indexer for a default indexed property.

See also  Class-based data member access, Class-based method call, Class-based property access, CLASS statement, FIRST-OBJECT attribute, LAST-OBJECT attribute, NEW function (classes), SUPER system reference, THIS-OBJECT system reference

Class-based property access

References a property of a class in order to read or write its value.

Syntax

```
[ [ class-type-name | object-reference ] : ]
property-name [ [ index | key ] ]
```
Class-based property access

class-type-name

The name of an ABL or .NET object type that defines the specified property as a static member. The use of `class-type-name` to access a static property is optional when you access the property from within the class hierarchy where it is defined. For more information, see the notes for this reference entry. You cannot use `class-type-name` to access an instance property. For more information on specifying object type names, see the Type-name syntax reference entry. You can use the unqualified class name with the presence of an appropriate USING statement.

object-reference

Specifies a reference to an instance of an ABL or .NET class (an object) that defines the specified property as an instance member. The use of `object-reference` to access an instance property is optional when you access the property from within the class hierarchy where it is defined. For more information, see the notes for this reference entry. You cannot use `object-reference` to access a static property. For information on specifying object references, see the reference entry for a Class-based object reference.

property-name

The name of an ABL or .NET property. Accessing a property is similar to accessing a variable data member. Also, like a data member, a property is defined in, and at, the level of a class definition. If it is an instance property, a separate copy exists for each instance of its defining class, for as long as the class instance exists. If it is a static property, only one copy exists for the defining class type during the entire ABL session, regardless if any instance of the class exists. A property is available inside or outside of the class hierarchy depending on its access mode. If and how a property can be read or written depends on a combination of its access mode and associated behavior defined for the property. For more information on ABL property definitions, see the DEFINE PROPERTY statement reference entry. For information on the definition of a .NET property, see its entry in Microsoft .NET, Infragistics, or another class library that defines it.

[ index | key ]

An index specifies an index into an ABL array property. A key specifies an indexer for a .NET indexed property. The brackets are a required part of the syntax.

If an array index is specified, it can be an integer value that identifies an element of an ABL array property, similar to an element of an ABL array data member (see the Class-based data member access reference entry).

If a key for a .NET property indexer is specified, it can be a value of any supported .NET data type that identifies the property value to reference. A .NET indexed property represents a group of properties, where the key is a value that indicates what member of the group is being referenced. A .NET indexed property can have more than one type of indexer that is overloaded according to the data type of its key, similar to a method that is overloaded by a single parameter. However, you cannot specify an AS data type with the key in order to identify a particular .NET indexer overload, as you can with a .NET method parameter (see the Parameter passing syntax overload reference entry). Also, some .NET indexed properties have indexers with multiple key values, each with its own data type. However, ABL only supports .NET indexed properties that have single-key indexers. So, you might be able to use some indexers for a property and not be able to use others.
Thus, ABL only recognizes a .NET property indexer if the property has a single-key indexer. If so, ABL selects the indexer using the ABL data type that you specify for the key, in order by the following criteria:

a) If the .NET data type of an indexer key is the default match for the specified ABL data type, ABL uses that key.

b) If there is no .NET indexer key that is a default match for the specified ABL data type, ABL uses the first key that it encounters where the .NET data type is an implicit data type mapping for the specified ABL data type.

For more information on how ABL data types map to .NET data types, see the Data types reference entry.

For example, if you specify an ABL INTEGER value for the key, and the indexer is overloaded by .NET System.Double, System.Byte, and System.Int32 keys, ABL uses the System.Int32 key to index the property. If the available overloading are System.Double, System.Byte, and System.Int16, ABL uses either the System.Byte or the System.Int16 key, which ever is encountered first.

ABL classes do not currently support the definition of indexed properties. So, you cannot access ABL properties using an indexer.

Examples

The following code fragment shows a reference to a public instance property (HighCustBalance) on an instance of the sample class, r-CustObj:

```abl
DEFINE VARIABLE rObj AS CLASS r-CustObj NO-UNDO.
rObj = NEW r-CustObj( ) NO-ERROR.
MESSAGE "High customer balance =" rObj:HighCustBalance VIEW-AS ALERT-BOX.
```

Once initialized, this instance property returns the highest balance for all Customer records in the sports2000 database.

The following code fragment shows a reference to a public static property (HighCustBalance) on the sample class type, r-CustObjStatic:

```abl
MESSAGE "High customer balance =" r-CustObjStatic:HighCustBalance VIEW-AS ALERT-BOX.
```

This static property similarly returns the highest balance for all Customer records in the sports2000 database without having to instantiate the class, as in the previous instance code.

For more information on these properties and the sample classes in which they are defined, see the examples in the CLASS statement reference entry.

Notes

- Using the appropriate property syntax, if the property is defined as both readable and writable, you can assign and otherwise read and write the value of a property in the same way as a variable data member of the same data type. If the property is read-only, you can only read the property value; if the property is write-only, you can only write a value to the property. For information on how .NET data types map to ABL data types when using .NET properties, see the Data types reference entry.
• When and how the value of a property can be read or written depends on the definition of special methods (accessors) that execute during property access. For more information on accessors for ABL properties, see the DEFINE PROPERTY statement reference entry. Note that even though the value written to a property appears to its SET accessor like a method parameter, the compatibility between the data type of the written value and the data type of the property follows the same rules as the assignment of data types for variables or data members. In other words, ABL attempts to identify an appropriate conversion when you assign a value to a property. For more information, see the Assignment (\(=\)) statement reference entry.

For more information on accessors for a .NET property, see its entry in Microsoft .NET, Infragistics, or another class library that defines the property. In C# documentation, the presence of a get accessor in the property signature means that the property is readable; the presence of a set accessor in the property signature means that the property is writeable. For example, the signature of the .NET HelpButton property indicates that it is both readable and writeable, because it shows both a get and a set accessor:

```csharp
public bool HelpButton { get; set; }
```

• If the property is defined as static, you can access the property whether or not an instance of its defining class exists.

• If you reference an available property within a static constructor, static method, or static property accessor that is defined in the same class or class hierarchy as the referenced property, the referenced property must also be defined as static; attempting to reference an instance property that is defined in the same class or class hierarchy as a referencing static member raises a compile-time error.

• You cannot use a class instance that is not equal to the THIS-OBJECT system reference to access a private or protected instance property that is defined in the same class, even though this property is defined in the instantiating class definition. In ABL, all private and protected properties are instance based and available only to members of a given instance of the class, including (for static properties) the "static instance" in the ABL session.

• From within an ABL class definition, you can reference any property that is both defined and available within the class hierarchy using its property-name without a qualifying object-reference (for instance properties) or class-type-name (for static properties). Optionally, you can use the THIS-OBJECT system reference as an object-reference to access any available instance property defined within the class hierarchy. If the property name is a reserved keyword, you must reference the property by qualifying the name with either its class-type-name or THIS-OBJECT as the object-reference. For more information, see the reference entry for the THIS-OBJECT system reference.

• From outside a class hierarchy, you must reference any available property using its property-name qualified by an object-reference to the class instance where the property is defined. You can only reference an available static property by referencing its property-name qualified by the class-type-name of the class that defines the property as static. The only properties defined in a class hierarchy that are available outside the hierarchy are properties defined as PUBLIC.

• You can access an abstract property either from within the class that defines it or on an object-reference defined as the type of the abstract class that defines it. Although an abstract property is defined without an implementation, at run time, the property is always
implemented in a derived class. So, any reference to an abstract property is always
resolved by the derived class that implements it.

- When you access an ABL property from within its own definition (from an accessor), this
access either directly accesses the property’s default memory or invokes an accessor,
depending on whether you are reading or writing the property and which accessor you are
accessing the property from. For more information, see the DEFINE PROPERTY
statement reference entry.

- .NET indexed properties can be overloaded only by the indexer, and ABL identifies the
overloading to use only by the definition of its indexer. Each overloading of an indexed
property can specify a different access mode (for example, private or public) and can have
different accessor method definitions. For example, one overloading of a property might
be read-only and another overloading of the property might be write-only. In general, all
overloadings of an indexed property share the same property data type. However, the data
type of the index key does not have to match the data type of the property.

- A .NET class can have a default indexed property. By convention, most default indexed
properties in the .NET Framework are named Item. Like some .NET languages, ABL
allows you to access the default indexed property by its name, like any other property.
However, ABL also allows you to access the default indexed property of a class by
specifying the indexer directly on object-reference, omitting the property name (see the
Class-based object reference reference entry in this book). For example, the .NET
System.Data.DataView class defines a default Item property that returns a .NET DataRow
given a record index. In ABL, therefore, the following indexed object references to a
DataView class instance are identical:

```
DEFINE VARIABLE rDataView AS CLASS System.Data.DataView.
DEFINE VARIABLE rRow  AS CLASS System.Data.DataRow.
. . .
rRow = rDataView[2].
rRow = rDataView:Item[2].
```

In .NET, the most common use of a default indexed property is to access an instance of a
class from a collection. Two examples are the .NET System.Data.DataTableCollection
and the System.Data.DataRow classes. For more information on working with .NET
collections in ABL, see OpenEdge Development: GUI for .NET Programming.

- When you access a property, the property accessor can raise the ERROR condition on the
statement that accesses the property. If this statement is defined with the NO-ERROR
option, you can locate the property error information using the ERROR-STATUS system
handle following statement execution, and you can read any returned error string using the
RETURN-VALUE function. Alternatively, you can catch the property error object using
a CATCH statement in the block that executes the statement. To access more
comprehensive error information for a .NET exception, use a CATCH statement instead
of the NO-ERROR option to handle .NET exceptions raised from accessing .NET
properties. For more information on handling .NET exceptions, see the sections on .NET
error handling in OpenEdge Development: GUI for .NET Programming.

See also  Class-based data member access, Class-based object reference, DEFINE PROPERTY
statement, Type-name syntax
CLASS statement

 Defines a user-defined class. A class defined with this statement represents a user-defined data type whose characteristics are defined by class members, including a set of class data members and properties that define class data, and a set of class methods and events that define class behavior. In addition to class members, a class definition can include special optional methods (one or more constructors and one destructor). It can also include class-scoped handle-based objects that provide private resources to the class, function prototypes for user-defined functions referenced by the class, and triggers to handle events for widgets and other handle-based objects defined by the class.

 You can instantiate a non-abstract class as an object using the NEW function (classes), NEW statement, the New( ) method of the Progress.Lang.Class class, or the DYNAMIC-NEW statement. Instantiating a class returns an object reference that provides access to instance members of the class. You can also access static members of a class without instantiating the class.

 Note: This statement is applicable only when used in a class definition (.cls) file. For more information, see the Notes section in this reference entry.

 Syntax

 CLASS class-type-name [ INHERITS super-type-name ]
 [ IMPLEMENTS interface-type-name [ , interface-type-name ] ... ]
 [ USE-WIDGET-POOL ]
 [ ABSTRACT | FINAL ] :
 class-body

 class-type-name

 Defines the type name for a user-defined class type. Specify an ABL class type name as described in the Type-name syntax reference entry. You can also specify an unqualified class name (without a package), but only if the class name represents the full type name for the class (that is, the class is not defined as part of a package).

 Note that you cannot specify Progress as the first component of the package name for any ABL user-defined class. For example, Progress.Inventory.UpdateInv is an invalid type name for a user-defined class and results in a compiler error.

 INHERITS super-type-name

 Optionally specifies the type name of a super class whose state and behavioral characteristics this user-defined class inherits. The new class becomes a subclass (derived class) of the specified super class and of every other super class in its class hierarchy. The super-type-name you specify can be an ABL or .NET class type name as described in the Type-name syntax reference entry. With an appropriate USING statement, you can also specify an unqualified class name (a class name without the ABL package or .NET namespace that completes the class type name).

 If super-type-name is an abstract class, in this class definition you must implement all the abstract members (properties, methods, and events) that you inherit unless you also define this class as abstract.
The following files must be found at compile time:

- For an ABL super class, the class definition (.cls) file.
- For a .NET super class, the assembly that contains the .NET class definition. OpenEdge places restrictions on the .NET classes you can inherit. For more information on the compilation requirements for inheriting .NET classes, see the Notes of this reference entry.

By default, a class definition inherits directly from the built-in ABL root class, Progress.Lang.Object. If you inherit from a .NET class, its .NET root class, System.Object, also inherits directly from Progress.Lang.Object.

**IMPLEMENTS** interface-type-name [ , interface-type-name ] ...

Optionally specifies the type name of one or more interfaces the new class implements. The new class must implement all properties and methods defined in the specified interfaces. Specify interface-type-name as an ABL or .NET interface type name as described in the Type-name syntax reference entry. With an appropriate USING statement, you can also specify an unqualified interface name (an interface name without the ABL package or .NET namespace that completes the interface type name).

For each interface that you implement, your class must implement all the properties, methods, and class events defined by the interface. If any super class in the hierarchy implements a property, method, or event defined by a specified interface-type-name, this satisfies the requirement to implement that property, method, or event in your class.

If multiple implemented interfaces define an identical member, they all share the same implementation of that member. Thus, ABL classes do not support .NET explicit interface members.

ABL must find the following files at compile time:

- For an ABL interface, the class definition (.cls) file that contains the interface definition. For more information on defining an ABL interface, see the INTERFACE statement reference entry.
- For a .NET interface, the assembly that contains the .NET interface definition. OpenEdge places restrictions on the .NET interfaces you can implement. For more information on the compilation requirements for implementing .NET interfaces, see the Notes of this reference entry.

**USE-WIDGET-POOL**

Directs the AVM to create an unnamed widget pool that is scoped to the class hierarchy of each instance of the class. When specified, all dynamic handle-based objects that are created in the class by and for instance class members are created by default in this unnamed widget pool. If the class contains static members, this option directs the AVM to create a separate unnamed widget pool that is scoped to the class for all dynamic handle-based objects created for or by these static class members in the session.

If methods or externally invoked procedures create their own unnamed widget pools, dynamic handle-based objects are created in the most locally scoped unnamed widget pool, regardless of this option. If no unnamed widget pools are created, either for the class (no USE-WIDGET-POOL option specified) or within any invoked procedure or method,
all dynamic objects are created by default in the session unnamed widget pool both for
instance and static members.

**Note:** When you define an unnamed widget pool in a method or external procedure, it is
scoped to that method or procedure. You can delete the widget pool within the
method or procedure using the DELETE WIDGET-POOL statement, or let the
AVM delete the widget pool when the method or procedure ends.

Within an instantiated class, any class in the class hierarchy that specifies the
USE-WIDGET-POOL directs the AVM to create one unnamed widget pool that all classes
in the class hierarchy share. The AVM deletes this unnamed widget pool when the class
instance is deleted (destroyed).

You can also define a named widget pool in a class definition file. If you define a named
widget pool, object instances are created in that widget pool only if you explicitly
reference the widget pool by name.

For more information about defining and using widget-pools, see the CREATE
WIDGET-POOL statement reference entry, and for creating widget pools within a class,
see *OpenEdge Development: Object-oriented Programming*.

**ABSTRACT**

Defines the class as abstract. An abstract class allows you to define any number of instance
property, method, or event members, as abstract. Abstract members are prototypes, similar
to interface members, without an implementation. Abstract members must be
implemented by a derived class to provide data or behavior, but they also function
polymorphically in the class hierarchy wherever they are still defined as abstract. So, for
example, an abstract property can be accessed or an abstract method can be called and the
result depends on its implementation further down in the class hierarchy. Also, whether or
not an abstract class defines abstract members, it must be inherited by a derived class.
Thus, you cannot directly instantiate an abstract class or define an abstract class as FINAL.

An abstract class can inherit from another abstract class or a non-abstract class, and it can
redefine any implemented methods that it inherits as abstract. However, it cannot redefine
any implemented properties or events that it inherits as abstract. Any redefined abstract
methods must, again, be implemented in a derived class.

If a non-abstract class inherits from an abstract class, it must implement all of the inherited
abstract members that are not already implemented in the abstract class hierarchy. An
abstract class can contain implemented class members, either exclusively or in addition to
abstract members. If an immediate subclass of an abstract class does not implement all of
its inherited abstract members, the immediate subclass must also be defined as abstract,
and a further derived class must implement the remaining abstract members.

**FINAL**

Indicates the class cannot be inherited by another class. That is, it cannot be used in the
INHERITS phrase in another class definition. Thus, a FINAL class cannot also be defined
as ABSTRACT. Define a class as FINAL when you do not want any of its state or behavior
overridden.

**class-body**

The body of a class definition is composed of the following types of elements:
• **Data members** — Class members that define instance or static data (or the state) for the class

• **Properties** — Class members that define instance or static data, similar to data members, but with the option of associated behavior

• **Methods** — Class members that define instance or static behavior for the class

• **Class events** — Class members that define instance or static events for the class

• **Constructors** — Special methods that define initialization for the class, at least one of which is invoked for the class when an instance (object) is created, and a separate one of which is invoked the first time a class with static members is referenced

• **Destructor** — A special method that defines finalization behavior and that is invoked when the AVM deletes the object using garbage collection or when you delete the object explicitly

• **Class-scoped handle-based objects** — Handle-based objects that are not class members, but can be defined in and privately scoped to provide certain resources to the class

• **Triggers** — ON statements, which are not class members, but can be defined in the class to handle events on class-scoped and other handle-based objects

• **User-defined function prototypes** — FUNCTION statements that are not class members but declare external user-defined functions referenced by the class

You can define these elements in any order. Only elements that are listed as class members contribute to the type definition of a class. The remaining elements provide weakly typed resources that are privately available to the class definition.

Define elements in the class body using the following syntax:

**Syntax**

```
[ data-member-definitions ]
[ property-definitions ]
[ method-definitions ]
[ event-definitions ]
[ constructor-definitions ]
[ destructor-definition ]
[ class-scoped-definitions ]
[ trigger-definitions ]
[ udf-prototype-definitions ]
END [ CLASS ].
```

**data-member-definitions**

Defines one or more data members of the class. Table 12 lists the types of data members you can define and their associated ABL DEFINE statement. Data members can be defined as instance or static members. An instance data member is
scoped to a particular class instance, while a static data member is scoped to the
duration of the ABL session.

Table 12: Class data member types

<table>
<thead>
<tr>
<th>Data member type</th>
<th>ABL DEFINE statement</th>
</tr>
</thead>
<tbody>
<tr>
<td>BUFFER object</td>
<td>DEFINE BUFFER statement</td>
</tr>
<tr>
<td>Class-based object</td>
<td>DEFINE VARIABLE statement (with the AS CLASS option, defines a variable as an object reference to a class or interface type)</td>
</tr>
<tr>
<td>DATASET object</td>
<td>DEFINE DATASET statement</td>
</tr>
<tr>
<td>DATA-SOURCE object</td>
<td>DEFINE DATA-SOURCE statement</td>
</tr>
<tr>
<td>HANDLE</td>
<td>DEFINE VARIABLE statement (a primitive type that can reference a handle-based object)</td>
</tr>
<tr>
<td>Primitive type</td>
<td>DEFINE VARIABLE statement (for example, INTEGER or HANDLE)</td>
</tr>
<tr>
<td>QUERY object</td>
<td>DEFINE QUERY statement</td>
</tr>
<tr>
<td>TEMP-TABLE object</td>
<td>DEFINE TEMP-TABLE statement</td>
</tr>
</tbody>
</table>

For more information on these data member types, and any class-related restrictions, see the associated ABL DEFINE statement reference entry listed in Table 12. For more information on accessing data members, see the Class-based data member access reference entry.

Note: If the data member is defined in a class that is derived from a .NET class, ABL imposes specific restrictions on the available names you can use to define data members. For more information, see the Notes of this reference entry.

**property-definitions**

Defines one or more instance or static property members of the class. If the class is abstract, an instance property can also be defined as abstract. Properties are similar to data members with the addition of behavioral and associated access control options. Like data members, an instance property is scoped to a particular class instance, while a static property is scoped to the duration of the ABL session. For more information on defining properties, see the DEFINE PROPERTY statement reference entry. For more information on accessing properties, see the Class-based property access reference entry.

Note: If the property is defined in a class that is derived from a .NET class, ABL imposes specific restrictions on the available names you can use to define properties. For more information, see the Notes of this reference entry.
method-definitions

Defines one or more instance or static method members of the class. If the class is abstract, an instance method can also be defined as abstract. A method is a named, callable block of ABL code that can return a value and that you can invoke like a procedure or a user-defined function (when it returns a value). You can define multiple overloaded methods with the same name, but with different parameter lists, and you can define a method that overrides or redefines a method of the same name and signature that is defined in a super class. Like data members and properties, an instance method is scoped to a particular class instance and a static method is scoped to the duration of the ABL session. For more information on defining methods, see the METHOD statement reference entry. For more information on calling methods, see the Class-based method call reference entry.

Note: If the method is defined in a class that is derived from a .NET class, ABL imposes specific restrictions on the available method names you can use to define methods. For more information, see the Notes of this reference entry.

event-definitions

Defines one or more instance or static event members of the class (class events). If the class is abstract, an instance event can also be defined as abstract. A class event allows the defining class to send notifications that some condition has been identified. Like data members, properties, and methods, an instance event is scoped to a particular class instance and a static event is scoped to the duration of the ABL session. For more information on defining class events, see the DEFINE EVENT statement reference entry. For more information on working with class events, see the “Class Events Reference” section on page 1953.

constructor-definitions

Defines one or more constructors for the class. Only one such constructor can be defined as static. An instance constructor is a special method that ABL invokes to initialize data for a new class instance when the object is instantiated using the NEW function (classes), NEW statement, or DYNAMIC-NEW statement. You can define multiple instance constructors distinguished (overloaded) by different parameter lists. You cannot invoke an instance constructor directly except from within the body of another constructor. If you do not define an instance constructor, ABL provides a default instance constructor that takes no parameters. A static constructor is a special method that ABL invokes to initialize static members defined by the class. You can define one static constructor that ABL invokes on the first reference to a class. If you do not define a static constructor, ABL provides a default static constructor. For more information on defining constructors, see the CONSTRUCTOR statement reference entry.

destructor-definition

Defines a destructor for the class. You can define only one destructor for a class. ABL invokes this destructor when the an instance of the class is deleted, either automatically during garbage collection or manually using the DELETE OBJECT statement. You cannot invoke a destructor directly. If not defined, ABL provides a default destructor. For more information on defining a destructor, see the DESTRUCTOR statement reference entry.
class-scoped-definitions

Defines class-scoped handle-based objects that are not data members, but provide certain resources that are privately scoped to the class definition. These resources include the statically defined widgets that support the OpenEdge GUI and certain statically defined handle-based objects, all of which are listed in Table 13.

Table 13: Class-scoped handle-based objects

<table>
<thead>
<tr>
<th>Data member type</th>

<tr>
<td>WORK-TABLE object</td>
<td>DEFINE WORK-TABLE statement</td>
</tr>
</tbody>
</table>

For more information on defining these class-scoped objects, and any class-related restrictions, see the associated ABL DEFINE statement reference entry.

trigger-definitions

Defines one or more ON statements that specify triggers for events on certain handle-based objects, which can include some of the class-scoped objects listed in Table 13. For more information on defining triggers, see the ON statement reference entry.

udf-prototype-definitions

Declares user-defined function prototypes for functions that are defined external to the class but referenced by methods and triggers defined in the class. For more information on defining user-defined function prototypes, see the FUNCTION statement reference entry.

END [ CLASS ]

 Specifies the end of the class body definition. You must end the class body definition with the END statement.
Examples

The following samples include three different sets of class and procedure definitions that provide similar functionality in different ways. Each class defines or inherits a ProDataSet data member (dsHighCustData) and a public class method (SetHighCustomerData( )) that populates the ProDataSet with selected fields in the sports2000 database from both a Customer record and related Invoice records, where the Customer has the highest recorded balance in the database and also has related invoices. Each implementation of SetHighCustomerData( ) also sets two public properties defined by its class (HighCustBalance and HighCustNum) to the highest database value for Customer.Balance and Customer.CustNum, and publishes a public class event defined by its class for each Customer record it encounters with related Invoice records. Each class defines or inherits additional data members to support its own instance of dsHighCustData, and also defines or inherits a public method (GetHighCustomerData( )) that returns dsHighCustData as an output parameter.

Each of the following sample class files or sets of class files implement this functionality:

1. r-CustObj.cls — Using instance members of an r-CustObj ABL class instance
2. r-CustObjStatic.cls — Using static members of the r-CustObjStatic ABL class type
3. r-CustObjAbstractImpl.cls and r-CustObjAbstract.cls — Using instance members of an r-CustObjAbstractImpl ABL class instance, some of which are abstract members inherited from the r-CustObjAbstract ABL abstract class

Each class or set of classes has an associated sample procedure that accesses the respective class and implements a similar application to display data stored by the class.

The following r-CustObj.cls sample class file shows many of the basic features of an ABL class definition. It defines only instance members and is defined as FINAL, meaning that it cannot be inherited by a subclass. This class sample also implicitly inherits from Progress.Lang.Object.

In this class, most of the data members, including the dsHighCustData ProDataSet and its supporting temp-tables, query, and data-sources, are defined as private, allowing access to its data primarily through its public properties and methods. However to demonstrate a public data member, the handle variable for dsHighCustData is defined as public. The class constructor attaches these data sources to the ProDataSet temp-table buffers and sets the handle variable (hHighCustData) for reference by the SetHighCustomerData( ) method to fill and refill the ProDataSet. (An application might need to call this method multiple times to refill the ProDataSet as database Customer.Balance values change.)
CLASS r-CustObj FINAL:
/* Public properties to return basic values for a customer with the highest balance */
DEFINE PUBLIC PROPERTY HighCustBalance AS DECIMAL INITIAL 0.0 NO-UNDO GET.
PRIVATE SET.
DEFINE PUBLIC PROPERTY HighCustNum AS INTEGER INITIAL ? NO-UNDO GET.
PRIVATE SET.
/* Public event to notify about Customers with Invoices */
DEFINE PUBLIC EVENT CustHasInvoices SIGNATURE VOID ( piCustNum AS INTEGER )
/* Public handle variable for the high customer ProDataSet */
DEFINE PUBLIC VARIABLE hHighCustData AS HANDLE NO-UNDO.
/* Private temp-tables for the high customer ProDataSet */
DEFINE PRIVATE TEMP-TABLE ttCust NO-UNDO LIKE Customer.
DEFINE PRIVATE TEMP-TABLE ttInv NO-UNDO LIKE Invoice.
/* Private ProDataSet for a single customer with the highest balance and its invoices */
DEFINE PRIVATE DATASET dsHighCustData FOR ttCust, ttInv
DATA-RELATION FOR ttCust, ttInv
RELATION-FIELDS (ttCust.CustNum, ttInv.CustNum).
/* Private query and data sources for the ProDataSet */
DEFINE PRIVATE QUERY qCust FOR Customer.
DEFINE PRIVATE DATA-SOURCE srcCust FOR QUERY qCust.
DEFINE PRIVATE DATA-SOURCE srcInv FOR Invoice.
/* Constructor to initialize handles and attach data sources */
CONSTRUCTOR r-CustObj () :
  hHighCustData = DATASET dsHighCustData:HANDLE.
  BUFFER ttInv:ATTACH-DATA-SOURCE( DATA-SOURCE srcInv:HANDLE ).
END CONSTRUCTOR.
/* Public method to get the current high customer data */
METHOD PUBLIC VOID GetHighCustomerData ( OUTPUT DATASET dsHighCustData BIND )
END METHOD.
/* Public method to set (or reset) the current high customer data */
METHOD PUBLIC VOID SetHighCustomerData () :
  hHighCustData:EMPTY-DATASET( ).
  FOR EACH Customer: /* Find Customer with highest balance */
    FIND FIRST Invoice WHERE Invoice.CustNum = Customer.CustNum NO-ERROR.
    IF AVAILABLE Invoice THEN DO:
      IF Customer.Balance > HighCustBalance THEN
        ASSIGN HighCustBalance = Customer.Balance
        HighCustNum = Customer.CustNum.
      CustHasInvoices:Publish( Customer.CustNum ).
    END.
  END.
QUERY qCust:QUERY-PREPARE("FOR EACH Customer "
  + "WHERE Customer.CustNum = " + STRING(HighCustNum) )
  hHighCustData:FILL( ).
END METHOD.
END CLASS.
To access the instance members of this class from outside its class definition, another class or procedure must instantiate the class and assign its object reference to a property or variable whose data type is the instantiated class type, for example:

```
DEFINE VARIABLE rObj AS CLASS r-CustObj NO-UNDO.
rObj = NEW r-CustObj( ) NO-ERROR.
```

This example uses the NEW statement to instantiate the class. You can also use the NEW function (classes) or New( ) method in an appropriate expression, or the DYNAMIC-NEW statement. You can then reference the public members of the class using the object reference, for example, calling a public instance method of the class:

```
rObj:SetHighCustomerData( ) NO-ERROR.
```

For more information on using object references, see the reference entry for a Class-based object reference.

To access instance members of a class from within the class definition or a derived class, you can typically reference the member without any prefix, like any local variable of a procedure or method. However, when the class member has the name of a reserved keyword, you must prefix the reference with THIS-OBJECT. For more information, see the reference entry for the THIS-OBJECT system reference.

The following r-CustObjProc.p sample procedure file displays data from an r-CustObj class instance as follows (with numbers corresponding to the numbered comments in the sample):

1. Defines a static ProDataSet object with a schema that is equivalent to the private dsHighCustData ProDataSet member defined by the r-CustObj class
2. Instantiates the r-CustObj class using the NEW statement, assigning its object reference to a variable (rObj) that the procedure uses to access this r-CustObj instance and all of its public members
3. Subscribes its internal procedure, CustHasInvoices_Handler, as a handler for the public CustHasInvoices event on the r-CustObj instance
4. Displays a message showing the default values of the r-CustObj public instance properties, HighCustNum and HighCustBalance
5. Calls the SetHighCustomerData( ) method on the r-CustObj instance, which initializes the r-CustObj public properties and private ProDataSet and publishes the CustHasInvoices event, causing the CustHasInvoices_Handler procedure to execute and display a message indicating each Customer that has invoices
6. Displays a message showing the initialized values of the r-CustObj public instance properties, HighCustNum and HighCustBalance
7. Calls the GetHighCustomerData( ) method on the r-CustObj instance to return its private ProDataSet member, dsHighCustData, as an output parameter, and storing the contents in its own equivalent ProDataSet object
8. Displays the contents of dsHighCustData in a down frame, showing fields from the Customer (ttCust) with the highest stored balance and related Invoice (ttInv) fields
The following r-CustObjStatic.cls sample class file provides functionality similar to r-CustObj.cls, but using static members instead. In addition, the class is not defined as FINAL. So, it can be inherited by an ABL subclass (not shown, here). This sample class also implicitly inherits from Progress.Lang.Object. Note that this class could include instance members as well. However, static members cannot reference instance members of the same class hierarchy; so, any instance members would have to support additional functionality, which could only be accessible using an instance of the class. The supported functionality, using static members, is available only as a function of the class type.
So, in this class, all the members are static. Most of the data members, including the 
dsHighCustData ProDataSet and its supporting temp-tables, buffers, query, and data-sources, 
are defined as protected, primarily allowing access to its data either by a subclass or through its 
public properties and methods from outside the class hierarchy. However to demonstrate a 
public data member, the handle variable for dsHighCustData is defined as public. The static 
class constructor (like the constructor in r-CustObj.cls) attaches these data sources to 
the ProDataSet temp-table buffers and sets the handle variable (hHighCustData) for reference by 
the SetHighCustomerData() to fill and refill the ProDataSet.

As another difference from r-CustObj.cls, note the use of the alternate static buffers 
(bHighCust, bCustomer, and bInvoice), which allow other static members, such as the static 
query and method members, to access the database Customer and Invoice tables. The default 
buffers of database tables cannot be accessed from a static class member because ABL treats 
these buffers implicitly as instance members of the same class.

r-CustObjStatic.cls

```abl
CLASS r-CustObjStatic:

/* Public static properties to return basic values for a customer with the 
highest balance */
DEFINE PUBLIC STATIC PROPERTY HighCustBalance AS DECIMAL INITIAL 0.0 NO-UNDO GET.
  PROTECTED SET.
DEFINE PUBLIC STATIC PROPERTY HighCustNum AS INTEGER INITIAL ? NO-UNDO GET.
  PROTECTED SET.

/* Public static event to notify about Customers with Invoices */
DEFINE PUBLIC STATIC EVENT CustHasInvoices SIGNATURE VOID ( piCustNum AS INTEGER )

/* Public static handle variable for the high customer ProDataSet */
DEFINE PUBLIC STATIC VARIABLE hHighCustData AS HANDLE NO-UNDO.

/* Protected static temp-tables for the high customer ProDataSet */
DEFINE PROTECTED STATIC TEMP-TABLE ttCust NO-UNDO LIKE Customer.
DEFINE PROTECTED STATIC TEMP-TABLE ttInv NO-UNDO LIKE Invoice.

/* Protected static ProDataSet for a single customer with the highest 
balance and its invoices */
DEFINE PROTECTED STATIC DATASET dsHighCustData FOR ttCust, ttInv 
  DATA-RELATION FOR ttCust, ttInv 
  RELATION-FIELDS ( ttCust.CustNum, ttInv.CustNum ).

/* Protected static buffers for the ProDataSet query and data sources */
DEFINE PROTECTED STATIC BUFFER bHighCust FOR Customer.
DEFINE PROTECTED STATIC BUFFER bCustomer FOR Customer.
DEFINE PROTECTED STATIC BUFFER bInvoice FOR Invoice.

/* Protected static query and data sources for the ProDataSet */
DEFINE PROTECTED STATIC QUERY qCust FOR bCustomer.
DEFINE PROTECTED STATIC DATA-SOURCE srcCust FOR QUERY qCust.
DEFINE PROTECTED STATIC DATA-SOURCE srcInv FOR bInvoice.

/* Static constructor */
CONSTRUCTOR STATIC r-CustObjStatic ():
  hHighCustData = DATASET dsHighCustData:HANDLE.
  BUFFER ttInv:ATTACH-DATA-SOURCE( DATA-SOURCE srcInv:HANDLE ).
END CONSTRUCTOR.
```
To access the static members of this class from outside of its class definition (and any derived class), you do not need to instantiate the class. You only need to reference the member using static type-name syntax, for example:

```plaintext
/* Public static method to get the current high customer data */
METHOD PUBLIC STATIC VOID GetHighCustomerData
  ( OUTPUT DATASET dsHighCustData BIND ):
END METHOD.

/* Public static method to set (or reset) the current high customer data */
METHOD PUBLIC STATIC VOID SetHighCustomerData ():
  hHighCustData:EMPTY-DATASET( ).
  FOR EACH bHighCust: /* Find first customer with highest balance */
    FIND bInvoice WHERE bInvoice.CustNum = bHighCust.CustNum NO-ERROR.
    IF AVAILABLE bInvoice THEN DO:
      IF bHighCust.Balance > HighCustBalance THEN
        ASSIGN HighCustBalance = bHighCust.Balance
        HighCustNum = bHighCust.CustNum.
        CustHasInvoices:Publish( bHighCust.CustNum ).
      END.
    END.
  END.
  QUERY qCust:QUERY-PREPARE("FOR EACH bCustomer 
                + "WHERE bCustomer.CustNum = " + STRING(HighCustNum) ).
     hHighCustData:FILL( ).
END METHOD.
END CLASS.
```

For more information on static type-name syntax, see the Type-name syntax, Class-based data member access, Class-based method call, and Class-based property access reference entries.

To access static members of a class from within the class definition or a derived class, you can typically reference the member without any prefix, like any local variable of a procedure or method. However, when the class member has the name of a reserved keyword, you must prefix the reference using static type-name syntax.

The following r-CustObjStaticProc.p sample procedure file displays static data from the r-CustObjStatic class type in a manner similar to how r-CustObjProc.p displays instance data from an r-CustObj class instance, except all references to public members are through the class type (r-CustObjStatic) instead of through an object reference (rObj in r-CustObjProc.p). Thus, r-CustObjStaticProc.p has no need to instantiate r-CustObjStatic. Otherwise, the application is exactly the same.
The following sample class files, r-CustObjAbstract.cls and r-CustObjAbstractImpl.cls, provide functionality similar to r-CustObj.cls, but using a combination of abstract and non-abstract instance members that are defined in the abstract class, r-CustObjAbstract, and inherited by the non-abstract class, r-CustObjAbstractImpl.

The r-CustObjAbstract.cls class file defines the r-CustObjAbstract abstract class. Its abstract members consist of most of the public members of the class, including properties, methods, and the class event. This class also implicitly inherits from Progress.Lang.Object.
In this class, all the data members (which are always non-abstract), including the dsHighCustData ProDataSet and its supporting handle variable, temp-tables, buffers, query, and data-sources, are defined as protected, allowing direct access to its data from any subclass that inherits from it or through its public properties and methods (once implemented) from outside the class hierarchy. The abstract class constructor (like the constructor in r-CustObj.cls) attaches the data sources to the ProDataSet temp-table buffers and sets the handle variable (hHighCustData) for reference by the subclass that implements the abstract SetHighCustomerData( ) method to fill and refill the ProDataSet. This constructor also subscribes a private method (CustHasInvoices_Handler( )) as a handler for the abstract CustHasInvoices event. This handler thus always responds to the event, no matter how it is implemented. Note that the class cannot publish the event, because it has not yet been implemented.

One public method, GetHighCustomerData( ), is implemented (not abstract) because its only function is to return dsHighCustData as an output parameter. If necessary, an abstract subclass can still override it again as abstract for implementation further down the class hierarchy, or it can simply be overridden by any subclass. The abstract method, SetHighCustomerData( ), is intended to be implemented any number of ways. For example, an alternative implementation could accumulate an actual Customer balance from related Invoice.Amount values instead of using the stored value of Customer.Balance, which does not necessarily match this total. For an example of this implementation, see the r-ICustObjectImpl2.cls sample class file, which is described in the Examples section of the INTERFACE statement reference entry.

Also, note the use of the protected alternate buffers (bCustomer and bInvoice). These buffers allow access to the database Customer and Invoice tables by certain protected class member definitions, including the ProDataSet query and data-sources, that cannot reference the default buffers of database tables. ABL implicitly treats the default buffers of database tables as private instance members of any class that references them; so they cannot be inherited along with any protected member definitions where they might be included. As such, the protected buffers allow any derived class to access the same buffers that are referenced in the protected member definitions it inherits.
CLASS r-CustObjAbstract ABSTRACT:

/* Public abstract properties to return basic values for a customer with the highest balance */
DEFINE PUBLIC ABSTRACT PROPERTY HighCustBalance AS DECIMAL NO-UNDO GET.
   PROTECTED SET.
DEFINE PUBLIC ABSTRACT PROPERTY HighCustNum AS INTEGER NO-UNDO GET.
   PROTECTED SET.

/* Public abstract event to notify about Customers with Invoices */
DEFINE PUBLIC ABSTRACT EVENT CustHasInvoices
   SIGNATURE VOID ( piCustNum AS INTEGER ).

/* Protected handle variable for the high customer ProDataSet */
DEFINE PROTECTED VARIABLE hHighCustData AS HANDLE NO-UNDO.

/* Protected temp-tables for the high customer ProDataSet */
DEFINE PROTECTED TEMP-TABLE ttCust NO-UNDO LIKE Customer.
DEFINE PROTECTED TEMP-TABLE ttInv NO-UNDO LIKE Invoice.

/* Protected ProDataSet for a single customer with the highest balance and its invoices */
DEFINE PROTECTED DATASET dsHighCustData FOR ttCust, ttInv
   DATA-RELATION FOR ttCust, ttInv
   RELATION-FIELDS (ttCust.CustNum, ttInv.CustNum).

/* Protected buffers for the ProDataSet query and data sources */
DEFINE PROTECTED BUFFER bCustomer FOR Customer.
DEFINE PROTECTED BUFFER bInvoice FOR Invoice.

/* Private query and data sources for the ProDataSet */
DEFINE PROTECTED QUERY qCust FOR bCustomer.
DEFINE PROTECTED DATA-SOURCE srcCust FOR QUERY qCust.
DEFINE PROTECTED DATA-SOURCE srcInv FOR bInvoice.

/* Constructor to initialize handles and attach data sources */
CONSTRUCTOR r-CustObjAbstract ( ):
   hHighCustData = DATASET dsHighCustData:HANDLE.
   BUFFER ttInv:ATTACH-DATA-SOURCE( DATA-SOURCE srcInv:HANDLE ).
   CustHasInvoices:Subscribe( CustHasInvoices_Handler ) NO-ERROR.
END CONSTRUCTOR.

/* Default private event handler for the abstract CustHasInvoices event */
METHOD PRIVATE VOID CustHasInvoices_Handler ( INPUT pArg AS INTEGER ):
   MESSAGE "Customer" pArg "has Invoices." VIEW-AS ALERT-BOX.
END METHOD.

/* Public method to get the current high customer data */
METHOD PUBLIC VOID GetHighCustomerData
   ( OUTPUT DATASET FOR dsHighCustData BIND ):
END METHOD.

/* Public abstract method to set (or reset) the current high customer data */
METHOD PUBLIC ABSTRACT VOID SetHighCustomerData ( ).
END CLASS.
The r-CustObjAbstractImpl.cls class file defines the non-abstract r-CustObjAbstractImpl class, which inherits r-CustObjAbstract and implements its abstract members. The class is not defined as FINAL. So, it can be inherited by an ABL subclass (not shown, here).

The abstract member implementations include initial values for the HighCustBalance and HighCustNum properties, the CustHasInvoices event so it can be published, and the SetHighCustomerData() method, which is implemented almost exactly the same as for r-CustObj, to set these properties, fill the ProDataSet, and publish the event when appropriate.

r-CustObjAbstractImpl.cls

```abl
 CLASS r-CustObjAbstractImpl INHERITS r-CustObjAbstract:

  /* Public properties implemented to return basic values for a customer with the highest balance */
  DEFINE OVERRIDE PUBLIC PROPERTY HighCustBalance AS DECIMAL INITIAL 0.0
    NO-UNDO
    GET.
    PROTECTED SET.
  DEFINE OVERRIDE PUBLIC PROPERTY HighCustNum AS INTEGER INITIAL ?
    NO-UNDO
    GET.
    PROTECTED SET.

  /* Public event implemented to notify about Customers with Invoices */
  DEFINE PUBLIC OVERRIDE EVENT CustHasInvoices
    SIGNATURE VOID (INPUT piCustNum AS INTEGER).

  /* Public method implemented to set (or reset) the current high customer data based on the stored value of Customer.Balance */
  METHOD OVERRIDE PUBLIC VOID SetHighCustomerData():

    hHighCustData:EMPTY-DATASET( ).
    FOR EACH Customer: /* Find Customer with highest balance */
      FIND FIRST Invoice WHERE Invoice.CustNum = Customer.CustNum NO-ERROR.
      IF AVAILABLE Invoice THEN DO:
        IF Customer.Balance > HighCustBalance THEN
          ASSIGN HighCustBalance = Customer.Balance
          HighCustNum = Customer.CustNum.
          CustHasInvoices:Publish( Customer.CustNum ).
        END.
      END.
    END.
    QUERY qCust:QUERY-PREPARE("FOR EACH bCustomer "
      + "WHERE bCustomer.CustNum = " + STRING(HighCustNum) ).
    hHighCustData:FILL( ).

  END METHOD.

END CLASS.
```

Note that from within r-CustObjAbstractImpl, members inherited from r-CustObjAbstract (such as hHighCustData and HighCustBalance) are accessed without any prefix, as if they were defined in the same class. You can access any inherited member of a super class this way. However, if an inherited instance member has the name of a reserved keyword, you must prefix the member reference with THIS-OBJECT. For more information, see the reference entry for the THIS-OBJECT system reference. For an inherited static member named with a reserved keyword, you must use static type-name syntax as previously described for the r-CustObjStatic class.
The following r-CustObjAbstractProc.p sample procedure file displays data from an instance of r-CustObjAbstractImpl in a manner similar to how r-CustObjProc.p displays data from an instance of r-CustObj. The only difference is in the event handler procedure (CustHasInvoices_Handler) which responds to the CustHasInvoice event in way that works more smoothly with the event handler provided by the r-CustObjAbstract class. Otherwise, the application is exactly the same.

For an example of an ABL class that inherits from a .NET class, see the WAIT-FOR statement (.NET and ABL) reference entry.

**Notes**

- You can terminate a CLASS statement with either a period (.) or a colon (:), but typically use a colon (:).
- A class definition (.cls) file can contain only one class definition that is optionally preceded by one or more USING statements and a ROUTINE-LEVEL ON ERROR UNDO, THROW statement. The complete class definition must begin with the CLASS
CLASS statement

The access mode for a class definition is always PUBLIC.

In effect, a user-defined class represents a unique data type. In ABL, you can use a class type much as you would any ABL built-in data type. You can define variables, parameters, return types, and class-based properties as a class type. These data elements can then hold a reference to a class instance (object reference). You can also assign an object reference to a temp-table field defined as the Progress.Lang.Object class type; but you cannot assign an object reference to a database table field. You can use the object reference to a class to access PUBLIC instance members of that class. For more information on object references, see the reference entry for a Class-based object reference. You can also use a class type name to access available static members of that class, whether or not an instance of the class exists. For more information on using class type names to access static class members, see the Class-based data member access, Class-based method call, Class-based property access, and Type-name syntax reference entries.

The class name part of class-type-name can be an ABL reserved keyword (such as Display). If it is a reserved keyword, note that ABL does not fully support user-defined class names that are identical to reserved keywords. For more information, see the Type-name syntax reference entry.

You can reference include files from within a class definition file. For more information about include files, see the reference entry for an { } Include file reference.

All built-in preprocessor directives are supported in class definition files.

All built-in preprocessor names are supported in class definition files. For a list of preprocessor names, see the reference entry for an { } Preprocessor name reference.

You cannot pass compile-time arguments to class definition files. However, you can pass compile-time arguments to include files referenced in a class definition file.

The compiled version of a class definition file is an r-code (.r) file. For more information, see the COMPILE statement reference entry.

You cannot run r-code compiled for a class definition file with the RUN statement.

PUBLIC and PROTECTED data members and properties within a class definition (.cls) file maintain their characteristics throughout the inherited class hierarchy. Thus, you cannot shadow (override) data members and properties in a subclass that are defined in a super class. In other words, you cannot define a data member or property in a subclass using the same name as a PUBLIC or PROTECTED data member or property defined in one of its super classes.

You can create an instance of a class using the NEW function, the New( ) method of the Progress.Lang.Class class, the NEW statement, or the DYNAMIC-NEW statement, and assign the object reference returned for that instance as the value of a data element defined to reference instances of that class type. You access a class instance, as well as its PUBLIC instance data members, properties, and methods, using its associated object reference. For more information on instantiating classes as objects, see the CONSTRUCTOR statement, NEW function (classes), New( ) method of the Progress.Lang.Class class, NEW...
The static members of a class are initialized with the first reference to its class type and just prior to execution of its static constructor, whether or not the class is instantiated in the process. These members remain in ABL session memory until the session ends or until the defining class is recompiled. Note that static data members and properties are not constant; the values of static data members can be changed like any data member, and the values of static properties can be changed as provided by the property definition. For more information on static member initialization, see the **CONSTRUCTOR** statement reference entry.

**ABL provides a system reference for the currently running instance of this class, called THIS-OBJECT. For more information, see the reference entry for the THIS-OBJECT system reference.**

If this class is a subclass of some super class, you can use the SUPER system reference within a class instance to access the PUBLIC and PROTECTED instance methods of all super classes within the inherited class hierarchy. For more information, see the reference entry for the **SUPER system reference**. You can also use static type-name syntax to access any static method that you redefine (override) in the class hierarchy. For more information, see the **Type-name syntax** reference entry.

You can store class definition r-code files in ABL procedure libraries. If the AVM encounters a procedure library on PROPATH, it will search the library for the specified r-code. However, you cannot execute r-code files stored in a procedure library that is not on PROPATH using the `procedure-library-path<<member-name>>` syntax.

You cannot define a NEW SHARED or NEW GLOBAL SHARED variable in a class definition (.cls) file.

You cannot use ActiveX controls within a class definition (.cls) file. However, you can use COM automation objects within a class definition (.cls) file, with any event handlers for a COM object defined in a procedure file.

For more information on class definition (.cls) files, see *OpenEdge Development: Object-oriented Programming*.

If you inherit a .NET class, implement a .NET interface, or otherwise access a .NET object type in a class definition, ABL must find the assembly that defines the .NET object type at compile time. For information on how ABL locates and identifies .NET object types, see the **Type-name syntax** reference entry.

If your user-defined class definition contains (instantiates) an ABL-derived .NET class, such as an ABL extension of Progress.Windows.UserControl, and the ABL-derived UserControl contains other .NET controls, you can subscribe to events on the contained .NET controls in two ways:

- Make the contained .NET controls PUBLIC, allowing clients of the container class to subscribe directly to events on these controls.

- Make the contained .NET controls PRIVATE and define PUBLIC ABL class events in the container class to publish on behalf of some subset of the events that .NET can publish on its contained .NET controls. Clients of the container class then subscribe...
to your publicly available ABL class events, allowing you to expose to clients only as much of the private .NET event behavior as you require.

For more information, see the sections on managing .NET events for controls contained by an ABL-derived .NET class in *OpenEdge Development: GUI for .NET Programming*.

- If you inherit a .NET class, the `GetType()` instance method (inherited from `System.Object`) returns incomplete information for the ABL part of the object.

- If you inherit a .NET class, you **cannot**:
  - Override the .NET `Dispose()` or `Finalize()` method
  - Define a method with certain reserved method names

For more information, see the **METHOD statement** reference entry.

- You **cannot**:
  - Inherit from a .NET class that is, itself, defined with any of the following .NET directives (as specified in C#):
    - `internal`
    - `private`
    - `sealed`
    - `static`
  - Define an ABL class that can become an additional part for a .NET `partial` class
  - Inherit from a .NET abstract class that defines an abstract indexed property
  - Inherit from a .NET generic class
  - Inherit from the following .NET class types or any class types that are derived from them:
    - `System.Delegate`
    - `System.Enum`
    - `System.Threading.Thread`
    - `System.ValueType`
  - Implement a .NET interface that:
    - .NET defines as `private` or `internal` (as specified in C#)
    - Is generic or that defines a generic method prototype
- Defines an indexed property prototype (including a default indexed property)

---

**CLEAR statement**

Clears the data for all fill-in fields in a frame. It also clears the colors for all widgets in a frame, except for enabled fill-ins.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
CLEAR [ FRAME frame ] [ ALL ] [ NO-PAUSE ]
```

**FRAME frame**

Represents the name of the frame containing the fill-in fields you want to clear. If you do not name a frame, CLEAR clears the default frame for the block containing the CLEAR statement.

**ALL**

Clears all occurrences and resets the current display position to the top of the frame for a down frame (a frame used to display several occurrences of the fields in the frame).

**NO-PAUSE**

Does not pause before clearing the frame.

**Example**

The r-clear.p procedure displays the ABL data types and their corresponding default formats. The procedure prompts you to enter values so you can see how ABL formats those values. If you answer YES, the AVM clears the values currently displayed so that you can enter new values.
CLOSE QUERY statement

Closes a query that was opened by a previous OPEN QUERY statement.

Syntax

```
CLOSE QUERY query
```

**query**

The name of an open query.

**Example**

The `r-c1sqry.p` procedure defines a query, `q-cust`, which it shares with `r-query.p`. Each time you choose the Ascending, Descending, or CustNum button, the procedure opens a new query for `q-cust`. To do this, the procedure must first close an open query for each `q-cust`. Therefore, the CLOSE QUERY statement is used in the CHOOSE trigger for each of these buttons.

Notes

- The CLEAR statement only clears fill-in fields. GUI widgets such as editors or radio-sets are not affected.
- The AVM automatically clears a single (down frame) whenever its block is iterated, and automatically clears a multi-frame (down frame) whenever it is full and its block is iterated.
- When clearing colors for a field-level widget in a frame, the CLEAR FRAME statement honors all widget attribute and option settings that specify how the widget inherits foreground or background colors from its containing frame.
CLOSE QUERY statement

**r-clsqry.p**

```plaintext
DEFINE NEW SHARED BUFFER x-cust FOR Customer.
DEFINE NEW SHARED QUERY  q-cust FOR x-cust.

DEFINE BUTTON b_quit LABEL "Quit"
  TRIGGERS:
    ON CHOOSE QUIT.
  END.

DEFINE BUTTON b_ascend  LABEL "Ascending".
DEFINE BUTTON b_descend LABEL "Descending".
DEFINE BUTTON b_num     LABEL "CustNum".

FORM b_ascend b_descend b_num b_quit
  WITH FRAME butt-frame ROW 1.

ON CHOOSE OF b_ascend DO:
  CLOSE QUERY q-cust.
  OPEN QUERY q-cust FOR EACH x-cust NO-LOCK BY x-cust.name.
  DISABLE ALL WITH FRAME butt-frame.
  RUN r-query.p.
END.

ON CHOOSE OF b_descend DO:
  CLOSE QUERY q-cust.
  OPEN QUERY q-cust FOR EACH x-cust NO-LOCK
  BY x-cust.name DESCENDING.
  DISABLE ALL WITH FRAME butt-frame.
  RUN r-query.p.
END.

ON CHOOSE OF b_num DO:
  CLOSE QUERY q-cust.
  OPEN QUERY q-cust FOR EACH x-cust NO-LOCK
  BY x-cust.CustNum.
  DISABLE ALL WITH FRAME butt-frame.
  RUN r-query.p.
END.

DO WHILE TRUE:
  ENABLE ALL WITH FRAME butt-frame.
  WAIT-FOR CHOOSE OF b_ascend, b_descend, b_num, b_quit.
END.
```

**r-query.p**

```plaintext
DEFINE SHARED BUFFER x-cust FOR Customer.
DEFINE SHARED QUERY  q-cust FOR x-cust.

GET FIRST q-cust.

DO WHILE AVAILABLE(x-cust):
  DISPLAY x-cust.name x-cust.custnum
     WITH FRAME cust-info CENTERED DOWN ROW 3 USE-TEXT.
  DOWN 1 WITH FRAME cust-info.
  GET NEXT q-cust.
END.
```

**Notes**

- If a query is closed, you cannot retrieve any more records for the query.
- Closing a query frees most resources used by the query.
CLOSE STORED-PROCEDURE statement

- After you close a query, you can reopen it with the OPEN QUERY statement. However, you cannot reuse the query’s buffers for a different table. For example, a buffer, buff1, is created for the customer table in a DEFINE QUERY or OPEN QUERY for the query, qry1. The query is run and closed. You cannot now DEFINE or OPEN qry1 with buff1 for the item table. You can reuse buffers with CREATE QUERY, but you must re-run QUERY-PREPARE.

- If you do not explicitly close a query, it is closed when another OPEN QUERY statement is executed for the same query name.

See also CURRENT-RESULT-ROW function, DEFINE QUERY statement, GET statement, NUM-RESULTS function, OPEN QUERY statement, REPOSITION statement

CLOSE STORED-PROCEDURE statement

For a non-ABL stored procedure, indicates that the procedure has completed execution and retrieves any return status. For a send-sql-statement stored procedure, closes the SQL cursor used by the procedure.

Syntax

```plaintext
CLOSE STORED-PROCEDURE procedure

integer-field = PROC-STATUS

WHERE PROC-HANDLE = integer-field
```

**procedure**

The name of the stored procedure that you want to close or the built-in procedure name, send-sql-statement.

**integer-field = PROC-STATUS**

Assigns the return value from a stored procedure to the specified integer field or variable (integer-field).

**WHERE PROC-HANDLE = integer-field**

An integer field or variable whose value uniquely identifies the stored procedure that produces the results returned from the data source or the SQL cursor of a send-sql-statement stored procedure.

Example

The PROC-STATUS clause of the CLOSE STORED-PROCEDURE statement allows the DataServer for ORACLE to retrieve the text of an ORACLE error message that was passed to raise_application_error. Use the ERROR-STATUS:GET-MESSAGE handle to retrieve the message, as shown in the following example:
Notes

- If you specified a PROC-HANDLE when you ran a stored procedure, you must specify the PROC-HANDLE when you close the stored procedure.

- If you do not specify a PROC-HANDLE, the CLOSE STORED-PROCEDURE statement will close the procedure if there is only one stored procedure running. If there is more than one stored procedure running, an error will be returned.

- You cannot close a send-sql-statement procedure until you have retrieved all row results.

- You can close all stored procedures at once with the following statement:

  ```
  RUN STORED-PROC closeallprocs.
  ```

- For more information on using this statement, see OpenEdge Data Management: DataServer for ODBC and OpenEdge Data Management: DataServer for Oracle.

See also

PROC-HANDLE function, PROC-STATUS function, RUN STORED-PROCEDURE statement

CODEPAGE-CONVERT function

Converts a string value from one code page to another.

Syntax

```plaintext
CODEPAGE-CONVERT
   ( source-string
     [ , target-codepage [ , source-codepage ] ]
   )
```

- **source-string**
  A CHARACTER or LONGCHAR expression to be converted.

- **target-codepage**
  A character-string expression that evaluates to the name of a code page. The returned character value is relative to `target-codepage`. The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management). If you supply a non-valid name, the
CODEPAGE-CONVERT function returns the Unknown value (?). Before returning a character value, the CODEPAGE-CONVERT function converts source-string from source-codepage to target-codepage. If you do not specify target-codepage, no code page conversions occur.

**source-codepage**

A character-string expression that evaluates to the name of a code page. The source-codepage specifies the name of the code page to which source-string is relative. The name that you specify must be a valid code page name available in the DLC/convmap.cp file. If you supply a non-valid name, the CODEPAGE-CONVERT function returns the Unknown value (?). The default value of source-codepage is the value of CHARSET attribute of the SESSION handle.

If source-string is a LONGCHAR variable, the source-codepage argument is not valid. In this case, the code page of the LONGCHAR variable is used as the source code page.

**Example**

This example assumes that the native code page of r-codpag.p is ibm850. It is written so that its embedded text strings are always converted to the internal code page of the ABL session (SESSION:CHARSET).

```r-codpag.p
DEFINE VARIABLE cp850string AS CHARACTER NO-UNDO INITIAL "text with umlaut (ä)".
DEFINE VARIABLE charsetstring AS CHARACTER NO-UNDO.
charsetstring = CODEPAGE-CONVERT(cp850string, SESSION:CHARSET, "ibm850").
FOR EACH Item NO-LOCK:
  IF LOOKUP(charsetstring, Item.CatDescription) > 0 THEN
    DISPLAY Item.ItemName.
  END.
```

**Notes**

- The CODEPAGE-CONVERT function returns the corresponding character string in the specified code page. By default, the value of SESSION:CHARSET is iso8859-1. You can set a different internal code page by specifying the Internal Code Page (-cpinternal) parameter. For more information, see OpenEdge Development: Internationalizing Applications and OpenEdge Deployment: Startup Command and Parameter Reference.

- This function is especially useful if you plan to run a procedure in an ABL session in which the SESSION:CHARSET code page is different from the native code page of the procedure.

- When you write procedures with ABL, you must use 7-bit (that is, ASCII) characters for field names and variable names. But you can use 8-bit and multi-byte characters, including Unicode, for data values such as character strings and constants. Thus, a procedure written and compiled on a system using one code page can be run on a system using another code page as long as you convert all embedded character strings to the internal code page. Using CODEPAGE-CONVERT as shown in the example allows your procedures to be virtually code page independent.

**See also** ASC function, CHR function, STRING function
COLOR phrase

Specifies a video attribute or color. In Progress Version 7 and later, the COLOR phrase is superseded by the FGCOLOR and BGCOLOR options in graphical user interfaces and by the PFCOLOR and DCOLOR options in character interfaces. The COLOR phrase is supported only for backward compatibility.

Note: Does not apply to SpeedScript programming.

Syntax

```
{ NORMAL
  | INPUT
  | MESSAGES
  | protermcap-attribute
  | dos-hex-attribute
  | { [ BLINK- ] [ BRIGHT- ]
    [ fgnd-color ] [ bgnd-color ]
  }
  | { [ BLINK- ] [ RVV- ] [ UNDERLINE- ] [ BRIGHT- ]
    [ fgnd-color ]
  }
  | VALUE ( expression )
}
```

NORMAL, INPUT, MESSAGES

The three standard colors ABL uses for screen displays. ABL uses NORMAL to display fields, INPUT to display input fields, and MESSAGES to display items in the message area.

Following are the NORMAL defaults:

- **Windows** — On a color monitor, the default colors are a blue background and a white foreground. On a monochrome monitor, the default colors are a standard background and foreground, depending on the monitor.

- **UNIX** — The default colors are the normal display mode of your terminal.

Following are the INPUT defaults:

- **Windows** — On a color monitor, the default colors are a light gray background and a blue foreground. On a monochrome monitor, the default underlines fields that require input.

- **UNIX** — The default colors depend on the type of terminal and how INPUT is defined in the protermcap file, but it is usually underlining.

Following are the MESSAGES defaults:

- **Windows** — On a color monitor, the defaults are the same as for INPUT. On a monochrome monitor, the default is reverse video.
• **UNIX** — The defaults depend on the type of terminal and how MESSAGES is defined in the protermcap file, but it is usually reverse video. (The protermcap file supplied with ABL supplies default attributes for NORMAL, INPUT, and MESSAGES for all defined terminals.)

**protermcap-attribute**

You use the `protermcap-attribute` option only if you are using UNIX. This is the name assigned to the attribute in the `protermcap` file (for example, RED, BLINK, etc.). See *OpenEdge Deployment: Managing ABL Applications* for a description of the `protermcap` file.

**dos-hex-attribute**

A hex string with a value of 00 through FF.

```
[ BLINK- ]  [ BRIGHT- ]  [ fgnd-color ]  [ bgnd-color ]
```

Names specific colors you want to use for the screen foreground and background. You use this option only if you are using Windows, and usually only if you use a color monitor. Table 14 lists the colors you can use for `fgnd-color` and `bgnd-color`.

**Table 14: Windows colors**

<table>
<thead>
<tr>
<th>Color</th>
<th>Abbreviation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Black</td>
<td>Bla, Blk</td>
</tr>
<tr>
<td>Blue</td>
<td>Blu</td>
</tr>
<tr>
<td>Green</td>
<td>Gre, Grn</td>
</tr>
<tr>
<td>Cyan</td>
<td>C</td>
</tr>
<tr>
<td>Red</td>
<td>Red</td>
</tr>
<tr>
<td>Magenta</td>
<td>Ma</td>
</tr>
<tr>
<td>Brown</td>
<td>Bro, Brn</td>
</tr>
<tr>
<td>Gray</td>
<td>Gra, Gry</td>
</tr>
<tr>
<td>Dark-Gray</td>
<td>D-Gra</td>
</tr>
<tr>
<td>Light-Blue</td>
<td>Lt-Blu</td>
</tr>
<tr>
<td>Light-Green</td>
<td>Lt-Gre</td>
</tr>
<tr>
<td>Light-Cyan</td>
<td>Lt-C</td>
</tr>
<tr>
<td>Light-Red</td>
<td>Lt-Red</td>
</tr>
<tr>
<td>Light-Magenta</td>
<td>Lt-Ma</td>
</tr>
<tr>
<td>Light-Brown</td>
<td>Lt-Bro</td>
</tr>
</tbody>
</table>
If `fgnd-color` is omitted, then the system uses the foreground corresponding to `NORMAL`. If `bgnd-color` is omitted, then the system uses the background corresponding to `NORMAL`. If `NORMAL`, `INPUT`, or `MESSAGES` is specified for `fgnd-color` or `bgnd-color`, then the system uses the foreground or background color of the specified standard color.

```
[ BLINK- ] [ RVV- ] [ UNDERLINE- ] [ BRIGHT- ] [ fgnd-color ]
```

Names specific attributes you want to use for the screen display. Use this option only if you are using Windows, and usually only if you use a monochrome monitor. Normally, you would never specify `fgnd-color`.

```
VALUE ( expression )
```

An expression with a value that results in one of the options in the `COLOR` phrase.

**Example**

The following procedure displays a random number of asterisks, in a random color, column, and row in 10 different occurrences. The `COLOR` statement displays the asterisks in one of the three colors stored in the elements of the `hilite` array. The `COLOR` phrase in this example is `VALUE ( hilite[ RANDOM( 1,3 )])`. The `DISPLAY` statement uses the color determined in the `COLOR` statement to display a random number of asterisks.

```r-colphr.p
DEFINE VARIABLE hilite AS CHARACTER NO-UNDO EXTENT 3.
DEFINE VARIABLE loop AS INTEGER NO-UNDO.

hilite[1] = "NORMAL".
hilite[2] = "INPUT". /* attribute to highlight */
hilite[3] = "MESSAGES".

REPEAT WHILE loop <= 10:
  FORM bar AS CHARACTER WITH ROW(RANDOM(3,17))
  COLUMN(RANDOM(5,50)) NO-BOX NO-LABELS
  FRAME bursts.
  COLOR DISPLAY VALUE(hilite[ RANDOM(1,3)]) bar
  WITH FRAME bursts.
  DISPLAY FILL("*",RANDOM(1,8)) @ bar WITH FRAME bursts.
  PAUSE 1 NO-MESSAGE.
  HIDE FRAME bursts NO-PAUSE.
  loop = loop + 1.
END.
```

**Notes**

- For an application to use this `COLOR` phrase, it must use the default color table in the installed environment.
- The system ignores the color phrase entry for overlay frames on spacetaking terminals.
COLOR statement

Indicates the video attribute or color for normal display or for data entry.

**Note:** Does not apply to SpeedScript programming.

### Syntax

```
COLOR [ DISPLAY ] color-phrase [ PROMPT color-phrase ]
{ field ... } { [ frame-phrase ] }
```

```
COLOR PROMPT color-phrase
{ field ... } { [ frame-phrase ] }
```

**DISPLAY**

 Indicates that you want to use a specific color when the system displays a field.

**PROMPT**

 Indicates that you want to use a specific color when the system prompts a user for input by an INSERT, PROMPT-FOR, SET, or UPDATE statement.

**color-phrase**

Specifies a video attribute or color. Following is the syntax for color-phrase:

### Syntax

```
{ NORMAL
  | INPUT
  | MESSAGES
  | protermcap-attribute
  | dos-hex-attribute
  | { [ BLINK- ] [ BRIGHT- ]
    [ fgnd-color ] [ bgnd-color ] }
  | { [ BLINK- ] [ RVV- ] [ UNDERLINE- ] [ BRIGHT- ]
    [ fgnd-color ] }
  | VALUE ( expression )
}
```
For more information on color-phrase, see the COLOR phrase reference entry. ABL ignores the color-phrase entry for overlay frames on spacetaking terminals.

field

The name of the field or fields for which you want to override the default colors.

frame-phrase

Specifies the overall layout and processing properties of a frame. For more information see the Frame phrase reference entry.

Example

This procedure highlights the item number and on-hand fields for items with an on-hand value less than 50. The variable hilite holds the video attribute (color) for highlighting. In this case, the system uses whatever attribute is used for the message area (such as reverse video, bright, or a color).

r-color.p

```
DEFINE VARIABLE hilite AS CHARACTER NO-UNDO INITIAL "messages".
/= Use standard messages attribute to highlight OnHand less than 50 */
FOR EACH Item NO-LOCK:
   DISPLAY Item.ItemNum Item.ItemName Item.OnHand WITH ATTR-SPACE.
   IF Item.OnHand < 50 THEN
   END.
```

Notes

- When the output destination is not the terminal, ABL disregards the COLOR statement.
- The COLOR statement does not automatically display a frame whose field’s color attribute is changing.
- Use one of these statements to reset a field to the ABL default colors:

```
COLOR DISPLAY NORMAL PROMPT INPUT field
```

Or:

```
COLOR DISPLAY NORMAL PROMPT INPUT field WITH FRAME frame
```

- If you run precompiled procedures on a spacetaking terminal, you must specify the frame field where a color or other video attribute is applied as, or is by default, ATTR-SPACE.
- If you write a procedure (for a non-spacetaking terminal) that uses color and you run it on a spacetaking terminal, the AVM does not display the colors. To display the colors, you must use the ATTR-SPACE option.
- Certain terminals, such as the WYSE 75, are non-spacetaking for some attributes and spacetaking for others.
On UNIX, if you specify a color or video attribute that is not defined for the terminal, the AVM uses normal display instead.

See also  COLOR phrase, DISPLAY statement, Frame phrase

COMBO-BOX phrase

Describes a combo-box widget. A combo-box represents a field or variable, and consists of a field value and an associated drop-down list of possible values.

**Note:** Does not apply to SpeedScript programming.

Syntax

```
COMBO-BOX
    [ LIST-ITEMS item-list ]
    [ LIST-ITEM-PAIRS item-pair-list ]
    [ INNER-LINES lines ]
    [ size-phrase ]
    [ SORT ]
    [ TOOLTip tooltip ]
    [ SIMPLE | DROP-DOWN | DROP-DOWN-LIST ]
    [ MAX-CHARS characters ]
    [ AUTO-COMPLETION [ UNIQUE-MATCH ] ]
```

Use the following syntax to specify a combo-box widget for displaying values in a browse column:

**Syntax**

```
COMBO-BOX
    [ LIST-ITEMS item-list ]
    [ LIST-ITEM-PAIRS item-pair-list ]
    [ INNER-LINES lines ]
    [ SORT ]
    [ DROP-DOWN | DROP-DOWN-LIST ]
    [ MAX-CHARS characters ]
    [ AUTO-COMPLETION [ UNIQUE-MATCH ] ]
```

**LIST-ITEMS item-list**

Specifies that the items appear in the drop-down list. `item-list` represents a comma-separated list of valid values for the field or variable.

**LIST-ITEM-PAIRS item-pair-list**

Specifies a list of label-value pairs. Each pair represents the label and value of a field or variable. When the drop-down list appears, it displays each pair’s label. Then, if the user selects a label, the AVM assigns the corresponding value to the field or variable. The syntax for `item-pair-list` is as follows:

**Syntax**

```
label , value [ , label , value ] ...```
**label**

A character string representing the label of the field or variable.

**value**

A value that the AVM assigns to the field or variable if the user selects the corresponding label.

**INNER-LINES** \(\text{lines}\)

Specifies the number of lines visible in the drop-down list for a DROP-DOWN or DROP-DOWN-LIST combo-box widget. The value for \(\text{lines}\) must be 3 or greater. If the number of lines you specify is less than the number of items in the drop-down list, the list is scrollable.

The INNER-LINES option in a SIMPLE combo-box definition is ignored.

**size-phrase**

Specifies the outside dimensions (width and height) of the combo-box widget and its drop-down list using the SIZE phrase. You must specify a SIZE phrase in the definition of a SIMPLE or DROP-DOWN combo-box widget. The syntax for the SIZE phrase is as follows:

**Syntax**

\[
\{ \text{SIZE} \mid \text{SIZE-CHARS} \mid \text{SIZE-PIXELS} \} \text{ width BY height}
\]

For more information, see the SIZE phrase reference entry.

**Note:** The \textit{height} value is ignored for DROP-DOWN and DROP-DOWN-LIST combo-box widgets. The height is always set to the height of a fill-in for the current font.

This option is invalid for combo-box browse columns. The AVM sets the ROW-HEIGHT-CHARS and ROW-HEIGHT-PIXELS attributes for a browse to the height of the combo-box, by default. You can override these settings after the browse is created.

**SORT**

Specifies that list items be sorted prior to display.

**TOOLTIP** \textit{tooltip}

Allows you to define a help text message for a text field or text variable. The AVM automatically displays this text when the user pauses the mouse button over a text field or text variable for which a tooltip is defined.

You can add or change the TOOLTIP option at any time. If TOOLTIP is set to “” or the Unknown value (?), then the tooltip is removed. No tooltip is the default. The TOOLTIP option is supported in Windows only.

This option is invalid for combo-box browse columns.
SIMPLE

Specifies a combo-box widget with a read/write edit control and a list that is always visible. This option is supported in graphical interfaces only, and only in Windows. If you specify a SIMPLE combo-box widget in a character interface, the AVM treats it as a DROP-DOWN-LIST combo-box widget.

This option is invalid for combo-box browse columns.

DROP-DOWN

Specifies a combo-box widget with a read/write edit control and a drop-down list that appears when you click the drop-down button. This option is supported in graphical interfaces only, and only in Windows. If you specify a DROP-DOWN combo-box widget in a character interface, the AVM treats it as a DROP-DOWN-LIST combo-box widget.

For combo-box browse columns, a drop-down button appears only when an editable combo-box column has focus. You can use a DROP-DOWN combo-box only for a CHARACTER column. If the current value of the combo-box is not a valid value in the combo-box’s item list, the AVM still displays the value in the combo-box’s edit control.

DROP-DOWN-LIST

Specifies a combo-box widget with a read-only edit control and a drop-down list that appears when you click the drop-down button. This is the default.

For combo-box browse columns, a drop-down button appears only when an editable combo-box column has focus. You can use a DROP-DOWN-LIST combo-box for a CHARACTER, DECIMAL, INTEGER, INT64, DATE, or LOGICAL column. If the current value of the combo-box is not a valid value, the AVM does not display the value in the combo-box’s edit control when the combo-box receives focus.

MAX-CHARS characters

The maximum number of characters the edit control can hold. The characters parameter must be a positive integer constant. If characters is zero or the Unknown value (?), MAX-CHARS is set to 255 characters by default.

Use MAX-CHARS with only SIMPLE and DROP-DOWN combo-boxes. It is ignored for DROP-DOWN-LIST combo-boxes. This option is supported in graphical interfaces only, and only in Windows.

AUTO-COMPLETION

Specifies that the edit control automatically complete keyboard input to the combo-box, based on a potential match, by searching through the items in the drop-down list. This option is supported in graphical interfaces only, and only in Windows.

UNIQUE-MATCH

Specifies that the edit control complete keyboard input to the combo-box based on a unique match. This option is supported in graphical interfaces only, and only in Windows.
Examples

The first example, `r-combo.p`, views a date field as a combo-box. When you run this procedure, you can choose a date value from the drop-down list. When you choose a new value, the VALUE-CHANGED trigger updates the value of out-string to an event associated with the new date value. The example initializes the drop-down list by building a comma-separated list of values and then assigning the string to the LIST-ITEMS attribute of the combo-box.

`r-combo.p`

```
DEFINE VARIABLE hist-date AS DATE NO-UNDO FORMAT "99/99/9999"
DEFINE VARIABLE hist-event AS CHARACTER NO-UNDO INITIAL
   "Declaration of Independence,Man walks on moon,Progress Version 7 ships".
DEFINE VARIABLE out-string AS CHARACTER NO-UNDO FORMAT "x(36)".

DEFINE FRAME main-frame
   hist-date out-string
   WITH NO-LABELS TITLE "Historic Events".

ON VALUE-CHANGED OF hist-date DO:
   out-string = ENTRY(SELF:LOOKUP(SELF:SCREEN-VALUE), hist-event).
   DISPLAY out-string WITH FRAME main-frame.
END.

ENABLE hist-date WITH FRAME main-frame.
APPLY "VALUE-CHANGED" TO hist-date IN FRAME main-frame.
WAIT-FOR WINDOW-CLOSE OF CURRENT-WINDOW.
```

The following example, `r-combo2.p`, builds a combo-box based on field values from a database. It defines triggers that allow you to change the value of the combo-box without displaying the drop-down list. They allow you to scroll through the values using the CURSOR-DOWN and CURSOR-UP keys or to jump to a specific value by typing its first letter.
When the drop-down list appears, if it contains the value associated with the field or variable, that value is initially highlighted. Otherwise, no value in the drop-down list is initially highlighted.

The LIST-ITEMS option of the COMBO-BOX phrase requires a list of items (possibly quoted, depending on the combo-box’s data type), such as ("a", "b", "c"), whereas the LIST-ITEMS attribute of a combo-box requires a quoted list of items, such as ("a, b, c"). Similarly, the LIST-ITEM-PAIRS option of the COMBO-BOX phrase requires a list of items (possibly quoted, depending on the combo-box’s data type), such as ("a", 1, "b", 2, "c", 3), whereas the LIST-ITEM-PAIRS attribute of a combo-box requires a quoted list of items, such as ("a, 1, b, 2, c, 3").

If you do not specify the LIST-ITEMS or LIST-ITEM-PAIRS option, the screen value of the variable or field becomes the null string (" "). To display or set values in the
combo-box, you must first set the LIST-ITEMS or LIST-ITEM-PAIRS attribute to assign a drop-down list that specifies the available values.

- If you specify the SORT option for a COMBO-BOX, then any items you add with the ADD-FIRST, ADD-LAST, or INSERT methods are added in sorted order rather than the order you specify.

- Windows allows the user to transfer focus to the drop-down list by pressing ALT and one of the letters in the label. This is called a mnemonic.

- When you use the SIMPLE and DROP-DOWN options to define a character-field or character-variable combo-box widget, the FORMAT string for the field or variable is ignored.

- Items in a combo-box are case insensitive.

**See also**  
Format phrase, SIZE phrase, VIEW-AS phrase

### COMPARE function

The COMPARE function compares two strings and lets you:

- Perform a raw compare, if desired
- Use a particular collation
- Turn case sensitivity on and off

COMPARE returns a LOGICAL value representing the result of the logical expression, where the comparison rules are defined by the combination of the operator, the comparison strength, and the collation.

**Syntax**

```
COMPARE ( string1 , relational-operator , string2 ,
               strength [ , collation ] )
```

- **string1**
  A CHARACTER or LONGCHAR expression that evaluates to the first string to be compared.

- **relational-operator**
  A CHARACTER expression that evaluates to one of the relational operators, which are: LT (or <), LE (or <=), EQ (or =), GE (or >=), GT (or >), NE (or <>), “BEGINS”, and “MATCHES”.

- **string2**
  A CHARACTER or LONGCHAR expression that evaluates to the second string to be compared.
**COMPARE function**

***strength***

A CHARACTER expression that evaluates to the ABL comparison strength or the International Components for Unicode (ICU) comparison strength to apply.

The ABL comparison strengths include:

- **RAW** — The AVM compares the two strings using the numeric values in the current code page.

- **CASE-SENSITIVE** — The AVM performs a case-sensitive comparison of the two strings using the numeric values in either the collation table specified in `collation`, or the collation table of the client. If you specify this strength with an ICU collation, the AVM applies the ICU TERTIARY strength.

- **CASE-INSENSITIVE** — The AVM performs a case-insensitive comparison of the two strings using the numeric values in either the collation table specified in `collation`, or the collation table of the client. If you specify this strength with an ICU collation, the AVM applies the ICU SECONDARY strength.

- **CAPS** — The AVM converts any lowercase letters in the two strings to uppercase letters, based on the settings of the Internal Code Page (`-cpinternal`) and Case Table (`-cpcase`) startup parameters, and then performs a raw comparison of the resulting strings. When neither string contains a wildcard character, this option behaves the same as the MATCHES operator.

The ICU comparison strengths include:

- **PRIMARY** — The AVM compares the base characters in the two strings.

- **SECONDARY** — The AVM compares the base characters and any diacritical marks in the two strings.

- **TERTIARY** — The AVM performs a case-sensitive comparison of the base characters and diacritical marks in the two strings.

- **QUATERNARY** — The AVM performs a case-sensitive comparison of the base characters and any diacritical marks in the two strings, and distinguishes words with and without punctuation. ICU uses this strength to distinguish between Hiragana and Katakana when applied with the ICU-JA (Japanese) collation. Otherwise, it is the same as TERTIARY.

**Note:** Use ICU comparison strengths only with ICU collations.

***collation***

A CHARACTER expression that evaluates to the name of an ABL collation table or ICU collation. By default, the AVM uses the collation rules you specify to compare characters and sort records. The collation rules specified with the Collation Table (`-cpcoll`) startup parameter take precedence over a collation specified for any database the AVM accesses during the session, except when the AVM uses or modifies pre-existing indexes. If you do not specify a collation with the `-cpcoll` startup parameter, the AVM uses the language collation rules defined for the first database on the command line. If you do not specify a database on the command line, the AVM uses the collation rules with the default name "basic" (which might or might not exist in the `convmap.cp` file).
If strength is not RAW or CAPS, the collation must be either an ABL collation table in the convmap.cp file or an ICU collation, and must be a valid collation table for the code page corresponding to the -cpinternal startup parameter.

### Notes
- If either or both strings evaluate to the Unknown value (?), COMPARE returns the value indicated in Table 15.

#### Table 15: Relational operators and the Unknown value (?)

<table>
<thead>
<tr>
<th>Relational operator</th>
<th>Only one string evaluates to ?</th>
<th>Both strings evaluate to ?</th>
</tr>
</thead>
<tbody>
<tr>
<td>LT (or &lt;)</td>
<td>FALSE</td>
<td>FALSE</td>
</tr>
<tr>
<td>LE (or &lt;=)</td>
<td>FALSE</td>
<td>TRUE</td>
</tr>
<tr>
<td>EQ (or =)</td>
<td>FALSE</td>
<td>TRUE</td>
</tr>
<tr>
<td>GE (or &gt;=)</td>
<td>FALSE</td>
<td>TRUE</td>
</tr>
<tr>
<td>GT (or &gt;)</td>
<td>FALSE</td>
<td>FALSE</td>
</tr>
<tr>
<td>NE (or &lt;&gt;)</td>
<td>TRUE</td>
<td>FALSE</td>
</tr>
<tr>
<td>BEGINS</td>
<td>FALSE</td>
<td>TRUE</td>
</tr>
<tr>
<td>MATCHES</td>
<td>FALSE</td>
<td>TRUE</td>
</tr>
</tbody>
</table>

- COMPARE returns the Unknown value (?) if one of the following occurs:
  - relational-operator does not evaluate to a valid value.
  - strength does not evaluate to a valid value.
  - collation does not evaluate to a collation table residing in the convmap.cp file.
  - collation evaluates to a collation table that is not defined for the code page corresponding to the -cpinternal startup parameter.

- LONGCHAR variable values are converted to -cpinternal for comparison and must convert without error, or the AVM returns an error.

- With BEGINS, the language-sensitive rules are used only when strength is not RAW or CAPS.

- With MATCHES, CASE-SENSITIVE is treated as RAW, CASE-INSENSITIVE is treated as CAPS, and the collation is never used.

## COMPILE statement

Compiles a procedure file or a class definition file. A compilation can last for a session, or you can save it permanently for use in later sessions (as an r-code file, which has a .r extension).
When you compile a class definition file, ABL compiles the class definition file identified in the COMPILE statement and all class files in its inherited class hierarchy, by default. You can direct ABL to compile only those class definition files in the class hierarchy that are not found in the cache, and cache any classes or interfaces it compiles during the session, by setting the MULTI-COMPILE attribute to TRUE.

**Note:** When you change the definition of a class, Progress Software Corporation recommends that you recompile all classes that inherit the modified class. This recommendation does not apply to method logic changes within a class.

After you compile a procedure file, you use the RUN statement to create an instance of the procedure, and you use a handle to access the procedure and its context. After you compile a class definition file, you use the NEW function (classes) to create an instance of the class, and you use an object reference to access the class-based object, as well as its data members, properties, and methods.

For more information about compiling procedure files, see *OpenEdge Getting Started: ABL Essentials*. For more information about compiling class definition files, see *OpenEdge Development: Object-oriented Programming*.
Syntax

```plaintext
COMPILE { procedure-pathname | class-pathname | VALUE ( expression ) } 
  [ ATTR-SPACE [ = logical-expression ] ]
  [ SAVE [ = logical-expression ]
    [ INTO { directory | VALUE ( expression ) } ] ]
  [ LISTING { listfile | VALUE ( expression ) }]
    [ APPEND [ = logical-expression ]
      | PAGE-SIZE integer-expression
      | PAGE-WIDTH integer-expression ]
  [ XCODE expression ]
  [ XREF { xreffile | VALUE ( expression ) }]
    [ APPEND [ = logical-expression ] ]
  [ XREF-XML { directory | filename | VALUE ( expression ) } ]
  [ STRING-XREF { sxreffile | VALUE ( expression ) }]
    [ APPEND [ = logical-expression ] ]
  [ STREAM-IO [ = logical-expression ] ]
  [ LANGUAGES ( { language-list | VALUE ( expression ) } ) ]
    [ TEXT-SEG-GROW = growth-factor ]
  [ DEBUG-LIST { debugfile | VALUE ( expression ) } ]
  [ PREPROCESS { preprocessfile | VALUE ( expression ) } ]
  [ NO-ERROR ]
  [ V6FRAME [ = logical-expression ]
    [ USE-REVVIDEO | USE-UNDERLINE ] ]
  [ MIN-SIZE [ = logical-expression ] ]
  [ GENERATE-MDS [ = logical-expression ] ]
```

**procedure-pathname | VALUE ( expression )**

Specifies the name and location of a procedure file you want to compile, where `procedure-pathname` is the literal procedure pathname and `expression` is a character expression that evaluates to the procedure pathname. This pathname can be a full (absolute) pathname or it can be a pathname (or procedure filename only) relative to PROPATH. The specified procedure filename must include the extension (.p or .w) whether you specify it alone or as part of a path. On UNIX, filenames are case sensitive, so you must enter them exactly as they are stored.

**class-pathname**

Specifies the name and location of a class definition file you want to compile. This can be a literal full (absolute) pathname or a literal pathname relative to PROPATH. If it is a relative pathname, the class or interface type name defined in the file must match the pattern of this relative pathname. If the type name is not defined with a package, the relative pathname must specify only the class filename. In all cases, the class filename must include the .cls extension. On UNIX, the `class-pathname` and corresponding class
or interface type name are also case sensitive and must match in letter case as well as spelling. For more information on packages and class or interface type names, see the Type-name syntax reference entry.

ATTR-SPACE  [ = logical-expression ]

Has no effect; supported only for backward compatibility.

XCODE  expression

Decrypts the source code in procedure-pathname or class-pathname, and any encrypted include files, using the decryption key expression.

When the COMPILE statement detects that a source file is encrypted, it performs the following checks:

- If the XCODE option is provided, then COMPILE uses the key specified by expression. If the key does not match the source file key, then the compilation fails with an error message. Use this option only when the encryption key is not the built-in (default) key or the encryption key for the session.

- If XCODE is not present, the COMPILE statement looks for a session-level encryption key in the XCODE-SESSION-KEY attribute of the SECURITY-POLICY handle. If COMPILE finds a session key and it does not match the source file key, then the compilation fails with an error message.

- If XCODE is not present and there is no session key, the COMPILE statement uses the default key. If the default key does not match the source file key, then the compilation fails with an error message. If a session key is in effect and you want a COMPILE statement to use the default key, then you must unset the XCODE-SESSION-KEY attribute by setting it to the Unknown value (?) before executing the COMPILE statement.

- The XCODE utility does not perform code page conversions and does not use the -cpinternal parameter when encrypting files. Therefore, the source code and key will use the default codepage of the operating system where you run the XCODE utility. If a different codepage is in effect where XCODE-SESSION-KEY is set, then codepage conversions may prevent the attribute key from matching the XCODE utility key and the compile fails. To prevent this case, use only US-ASCII characters, which are found in all code pages below code point 128.

Include files that are not encrypted are included and compiled in the standard manner.

Having the decryption key does not allow you to examine a decrypted version of the source code.

Note: You cannot use XCODE with the XREF, XREF-XML, STRING-XREF, or LISTING options together. Also, if the DEBUG-LIST option is used with an encrypted source file, the resulting debug file will only contain a notice that the source file is encrypted.

STREAM-IO  [ = logical-expression ]

Specifies that all output from the compiled procedure or class is formatted for output to a file or printer. This means that all font specifications are ignored and all frames are treated
as if they had the USE-TEXT option given. This produces a platform-independent output appropriate for printing.

If you specify a logical-expression, its value determines whether the STREAM-IO option is activated. If the logical-expression is evaluated to the Unknown value (?), a run-time error occurs.

SAVE [ = logical-expression ] [ INTO { directory | VALUE ( expression) } ]

Produces a file that contains the r-code for the procedure or class you are compiling.

When you compile a class definition file with the SAVE option, ABL produces an r-code file for the class definition file and all class files in its inherited class hierarchy. For example, if you compile a class definition file that has two classes in its inherited class hierarchy, ABL compiles three files and produces three r-code files.

These r-code files are saved across ABL sessions. If you do not use the SAVE phrase, the COMPILE statement produces r-code for the source procedure or class, but the r-code is not saved across ABL sessions. This r-code is a session-compile version of the procedure or class.

If you specify a logical-expression, its value determines whether the SAVE option is activated. If the logical-expression is evaluated to the Unknown value (?), a run-time error occurs.

The COMPILE SAVE statement produces r-code files with the name procedure-pathname.r or class-pathname.r, where procedure-pathname is the pathname of a procedure source file without the filename extension, and class-pathname is the pathname of a class source file without the filename extension. ABL ignores the filename extension of a procedure or class definition file and always creates r-code files that use the same filename with a .r extension. For example, if you supply a filename of test, test.p, or test.cls, COMPILE SAVE produces an r-code file with the name test.r. If you specify a filename of test.bp, COMPILE SAVE still produces an r-code file with the name test.r.

Caution: Where both procedure and class definition files compile to a .r file, be sure to use distinct filenames. If you have a procedure file and a class definition file with the same name, and you compile them both with COMPILE SAVE, the first .r file will be overwritten by the second .r file.

By default, the r-code file is stored in the same directory as the source file. The r-code files for inherited (super) class definition files are also stored in the same directory as their respective source files.

If you use the SAVE INTO phrase, r-code files produced by a compilation can be saved in a different directory. See the Examples section and the Notes section of this reference entry for more information.

On UNIX and Windows, a newly created r-code file replaces any existing r-code file of the same name.

LISTING { listfile | VALUE ( expression ) }

Produces a compilation listing that includes:
• The name of the file containing the procedure or class you compile
• The date and time at the start of the compilation
• The number of each line in the procedure or class file
• The block number where each statement belongs
• The complete text of all include files (except encrypted include files) and the names of any subprocedures and user-defined functions

The listfile or VALUE ( expression ) identifies the name of the file in which you want to store the Compiler listing. If expression evaluates to the Unknown value (?), then ABL ignores the LISTING option.

APPEND \[ = logical-expression \]

Appends the current listing to the contents of the listing file. If you do not use the APPEND option, ABL creates a new listing file, replacing any file of the same name.

If you specify a logical-expression, its value determines whether the APPEND option is activated. If the logical-expression is evaluated to the Unknown value (?), a run-time error occurs.

PAGE-SIZE integer-expression

Identifies the number of lines to a page in the listing file. The default page size is 55 and integer-expression must be between 10 and 127, inclusive.

PAGE-WIDTH integer-expression

Identifies the number of page columns in the listing file. The default page width is 80, and integer-expression must be between 80 and 255, inclusive. Add at least 12 spaces to the page width when you type the file. This allows you to list information that precedes each line of code, ensuring that the file appears in the listing output exactly as you typed it.

XREF \{ xreffile | VALUE ( expression ) \} [ APPEND \[ = logical-expression \] ]

Writes cross-reference information between procedures and ABL objects, or between class or interface definition files and ABL objects, to the file xreffile or VALUE ( expression ). If expression returns the Unknown value (?), then ABL ignores the XREF option.

Note: You cannot use the XREF and XCODE options together. That is, you cannot create a cross-reference listing from code that is encrypted.

Cross-referenced objects include procedure and include files, user-defined functions, classes, methods, database tables, shared temp-tables, fields, variables, frames, and character strings. XREF generates one unformatted, blank-separated line in xreffile for each referenced object. Each line has the following format:

source-name file-name line-number reference-type object-identifier
The source-name is the name of the procedure or class file you compile with the COMPILE XREF statement. The file-name is the name of the file with the referenced code. The line-number is the line number of the statement in file-name that contains the referenced object. The reference-type is the type of reference in the code (such as ACCESS or UPDATE), and the object-identifier is the ABL object being referenced.

Note: If file-name is an include file, source-name is the file that includes the include file.

The possible reference types and object identifiers appear in Table 16.

Table 16: Reference types and object identifiers (1 of 5)

This is the syntax for `data-member-name`:

**Syntax**

```
variable-name | { [ dataset-name ] table [ field ] }
```

This is the syntax for `invocation-parameter`:

```
```
The invocation parameters will be listed for every constructor or method invocation that has arguments. If a method or constructor is overloaded, invocation parameters can be used to determine which version of the method or constructor is being invoked. If the compiler has not resolved the method call (that is, it has deferred resolution to run time), one or more of the invocation parameters may be identified as TABLE REFERENCE, DATASET REFERENCE, or RUNTYPE. This label indicates that the argument being passed matches the type of the corresponding parameter in more than one of the candidate overloads.

In the case of TABLE REFERENCE or DATASET REFERENCE, the parameter may be a static temp table or dataset or a handle to a temp table or dataset.

RUNTYPE means that the compiler cannot determine the type because the argument is, for example, BUFFER-FIELD(1):BUFFER-HANDLE.

EXTENT without a constant integer value following it may simply mean that the parameter is defined as indeterminate, or it may mean that the call has not been resolved and the candidate overloads have arrays of different extents at that position in the parameter list.

The following notes describe more usage information for Table 16:

- PUBLIC-DATA-MEMBER indicates that a line of code in a client of a class references a class public data member through an object reference. For example: localvar = MyInstance:PubMember. Properties are treated similarly.

- In contrast to PUBLIC-DATA-MEMBER, INHERITED-DATA-MEMBER indicates that a line of code references a data member inherited by the class in which the reference appears. DATA-MEMBER in an UPDATE or ACCESS entry indicates that a line of code references a temp-table or related object that has been defined in the class in which the reference appears. Properties are treated similarly.

- There will be quotes around the name of a class or interface if its package name includes a space.

- In the CLASS entry, INHERITS inherited-class-name indicates the immediate super class of the class, if any exists. If the super class inherits from one or more classes, the names of these classes will appear following the name of the immediate super class of the compiled class. Each inherited class name will be separated from the preceding one by a space.
• XREF output includes “STRING” reference type entries. In addition to the strings that are already logged (variable names, function and procedure names, and so on), the XREF output will now include “STRING” reference type entries for class names, inherited class names, implemented interface names, method names, property names, and data member names.

• If a class has a super class but does not explicitly execute the SUPER statement in its constructor, the ABL compiler adds an implicit SUPER invocation to the r-code. When this happens, there will be an INVOKE entry generated for the implicit SUPER invocation. This entry indicates that the name of the method being invoked is super-class-type-name.class-name (the constructor name). Instead of a line number, the entry will use the label IMPLICIT.

• As is the case with PROCEDUREs and FUNCTIONs, the entry for a method, constructor, or destructor will be made during compilation of the element’s END statement. Therefore, a METHOD entry will appear after the entries for items encountered within the method, and the line number given will be the line number of its END statement.

• Note that field for REFERENCE is optional. It will not appear if the corresponding line of code is either VALIDATE temp-table or RELEASE temp-table.

• If a class has as a data member an ABL handle and code uses that handle to call a built-in ABL method or to set or get a built-in attribute, the XREF output will include just an ACCESS entry and the entry will identify only the name of the handle data member, not the method or attribute involved. (This is similar to how XREF handles SHARED variables that are handles.)

• The XREF entry for CAST will include the source type if it is possible to determine the source type at compile time. If not, it will include only the target type.

• If you specify the APPEND option, the cross-reference information is appended to an existing file. The first line of cross-reference information for a procedure contains the object identifier for the COMPILE reference type. This allows you to easily find where the information for each compilation begins. If you specify a logical-expression, its value determines whether the APPEND option is activated. If the logical-expression is evaluated to the Unknown value (?), a run-time error occurs.

• Temp-tables must be shared to be included in XREF output. Locally defined temp-tables are not considered cross-referenced objects and are therefore not included in XREF output.

XREF-XML { directory | filename | VALUE ( expression ) }

Writes the cross-reference string information to a formatted XML file. The standard XREF option writes the information to an unformatted text file. The XREF-XML option provides structured output that is formatted with whitespace for easier parsing by humans. More importantly, this option exposes the cross-reference information in a format that developers can exploit with custom-built tools or visualize in a ProDataset or a .NET dataset.

Table 16 and the accompanying documentation in the XREF option section defines the cross reference and identifier labels used with both the standard XREF and the XREF-XML options.
For compiling a single procedure or class, you can provide a filename for the XML output file. However, this output file is overwritten each time the compiler needs to compile a linked class or procedure.

For compiling several procedures and classes in a single compile statement, supply a directory for the XREF-XML option. The XREF-XML option uses this directory and a standard naming convention to capture the cross-reference information from multiple procedures and classes in separate files. Contrast this with the APPEND mode used by the XREF option.

When a directory is supplied, the compiler takes the root name of the procedure or class being compiled and creates a cross-reference file with this name and a .xref.xml file extension (sourcefilename.xref.xml). It stores it in the directory path specified, creating any necessary subdirectories that do not exist. If the main directory specified does not exist, then an error is raised.

If the filename supplied to the compiler begins with a relative path, then the directory name supplied to the XREF-XML option will include that relative path. For example, suppose your Unix PROPATH is /projectA/source and you run this COMPILE statement:

```
COMPILE test/procedureA.p XREF-XML /projectA/xref
```

The COMPILE statement will look for the source file /projectA/source/test/procedureA.p and place the XREF-XML output in /projectA/xref/test/procedureA.xref.xml (if the source file successfully compiles).

If the source file uses a full path, then the XREF-XML option stores the output in the directory provided, ignoring the path of the source file.

You may want to check for possible filename collisions before using this option. For example, if you have myCode.p and myCode.cls, both will use the myCode.xref.xml output file, destroying some of your cross-reference information.

When you use the VALUE option to provide a filename or directory path, if VALUE returns the empty string or the Unknown value (?), then the compiler ignores the XREF-XML option.

If class definition source files in a class hierarchy are in different directories, matching subdirectories will be created for them under the provided XREF-XML directory.

The XML Schema used with XREF-XML output files is stored in the following location: $DLC/properties/schemas/xrefdxxx.xsd. The XXXX portion of the file name indicates the version number of the file.

You can see an example on the difference between XREF and XREF-XML output in the Examples section at the end of the COMPILE statement reference.

**Note:** You cannot use the XREF-XML option with the XREF option or with the XCODE option at the same time.
STRING-XREF \( \{ sxreffile \mid VALUE(\ expression) \} \) 
\[
[\text{APPEND}[\ = \ logical-expression \ ]]
\]

Wipes cross-reference string information between procedures and ABL objects, or between class definition files and ABL objects, to the file \( sxreffile \) or \( VALUE(\ expression) \). If \( expression \) evaluates to the Unknown value (?), ABL ignores the STRING-XREF option.

<table>
<thead>
<tr>
<th>String Xref Version ( x.y ) source-file code-page</th>
</tr>
</thead>
</table>

The \( x.y \) is a major.minor version number, where a major version change implies a formatting change that will not be backward compatible with older versions of TranManII. The \( source-file \) is the name of the file from which the strings are extracted. The \( code-page \) is the code page with which the file was written.

The line for each string appears in the following format:

\[
\text{line-number object-name string max-length string-justification statement-type detail-info}
\]

The \( line-number \) is the same as \( line-number \) in the standard XREF file. The \( object-name \) is the name of the object with which the string is associated. The \( max-length \) and \( string-justification \) come from the string attribute (either explicit or implicit) and reflect the attributes applied to the string as it is entered into the text segment.

The \( statement-type \) describes the type of statement in which the string appears. Only one statement type appears in a given string’s output line. The values in the following table are possible:

<table>
<thead>
<tr>
<th>Statement type values</th>
</tr>
</thead>
<tbody>
<tr>
<td>ASSIGN</td>
</tr>
<tr>
<td>CASE</td>
</tr>
<tr>
<td>CREATE</td>
</tr>
<tr>
<td>DEF-BROWSE</td>
</tr>
<tr>
<td>DEF-BUTTON</td>
</tr>
<tr>
<td>DEF-FRAME</td>
</tr>
<tr>
<td>DEF-IMAGE</td>
</tr>
<tr>
<td>DEF-MENU</td>
</tr>
</tbody>
</table>

*Note:* Any statement type that is not included in the preceding list will appear as OTHER.

The \( detail-info \) is one or more detail tags that specify more specifically where the string appears in the statement. The values in the following table are possible:
The NON-ALPHA tag indicates that a string consists entirely of blanks or digits. The FORMAT tag is followed by one of the following tags: CHAR, NUMERIC (includes decimal and integer), DATE, or BOOL. These tags indicate the type of format. When a string can appear in only one place in a statement, no detail tag appears.

Table 17 shows the valid combinations of statement types and detail tags.

<table>
<thead>
<tr>
<th>Statement type</th>
<th>Detail tags</th>

<td>FORMAT</td>
</tr>
</tbody>
</table>
LANGUAGES ( { language-list | VALUE ( expression ) } )

Identifies which language segments to include in the compiled r-code. The language-list is a colon-separated list of language names used to generate each text segment. If you specify VALUE ( expression ), the expression must evaluate to a comma-separated list of language names. If expression evaluates to the Unknown value (?), then ABL ignores the LANGUAGES option.

Translated character strings for each specified language are read from the translation database and are stored in segments within the r-code. For example:

```
COMPILE myfile.p LANGUAGES
(French-Canadian:French:English,Portuguese:Spanish,
```

If you use an expression to specify language-list, you must use the VALUE option. For example:

```
COMPILE myfile.p LANGUAGES (VALUE(char-var)).
/* char-var = "French-Canadian:French:English,Portuguese:Spanish,
 New-York:American:English" */
```

In this example, the compiler searches the translation database for French-Canadian translations. If a French-Canadian translation is not found, the compiler searches for a
French translation. If a French translation is not found, the compiler searches for an English translation. If an English translation is not found, the compiler uses the strings from the source code.

This example generates four text segments: French-Canadian, Portuguese, New-York, and the unnamed (default) text segment. The first language name in each `language-list` argument designates the name of the text segment and specifies the first language that the compiler looks up in the translation database. As a result, it is possible to create a text segment whose name has no relationship to the languages it is composed of. For example, the following argument creates a text segment named `BABEL`:

```plaintext
LANGUAGES(BABEL:French:Spanish:Italian:German)
```

Provided there is no language named BABEL in the translation database, the strings in this text segment would be either French, Spanish, Italian, or German, depending on which strings have translations in which languages.

**TEXT-SEG-GROW = growth-factor**

Specifies the factor by which ABL increases the length of strings. When you develop an application that is going to be translated, it is important to allow for the growth of the text in your widgets. If you use the TEXT-SEG-GROW option, ABL increases the size of the text strings when it compiles your application.

ABL uses the following formula to determine the length of strings:

\[
New\-\text{length} = \text{Actual}\-\text{length} \times \left[ 1 + \left(\frac{\text{growth-factor}}{100} \times \frac{\text{table-value}}{100}\right) \right]
\]

Where:

- `New-length` is the new string length.
- `Actual-length` is the actual string length.
- `growth-factor` is the value specified with the TEXT-SEG-GROW option.
- `table-value` is the appropriate percentage from the following table:

<table>
<thead>
<tr>
<th>String length</th>
<th>Expansion percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>1–10 characters</td>
<td>200%</td>
</tr>
<tr>
<td>11–20 characters</td>
<td>100%</td>
</tr>
<tr>
<td>21–30 characters</td>
<td>80%</td>
</tr>
<tr>
<td>31–50 characters</td>
<td>60%</td>
</tr>
<tr>
<td>51–70 characters</td>
<td>40%</td>
</tr>
<tr>
<td>More than 70 characters</td>
<td>30%</td>
</tr>
</tbody>
</table>
For example, if you have a text string that is 25 characters and you specify a growth-factor of 50, ABL applies the formula as follows and defines the New-length as 35:

\[
\text{New-length} = 25 \times (1 + (80/100 \times (50/100)))
\]

**Note:** TEXT-SEG-GROW is supported only when you also use the LANGUAGES option.

**DEBUG-LIST** `{ debugfile | VALUE ( expression ) }`

Writes the debug listing to the file `debugfile` or `VALUE ( expression )`. If `expression` evaluates to the Unknown value (?), then ABL ignores the DEBUG-LIST option. The `debugfile` consists of a line-numbered listing of the procedure with the text of all preprocessor include files, names, and parameters inserted.

**PREPROCESS** `{ preprocessfile | VALUE ( expression ) }

Preprocesses the procedure or class definition file and writes the preprocessed source code to the file `preprocessfile` or `VALUE ( expression )`. If `expression` evaluates to the Unknown value (?), ABL ignores the PREPROCESS option. The `preprocessfile` is a text file that contains a final version of your source code after all include files have been inserted and all text substitutions have been performed.

**NO-ERROR**

Specifies that any errors that occur as a result of the compilation are suppressed. After the COMPILE statement completes, you can check the ERROR and WARNING attributes of the COMPILER system handle to determine whether an error has occurred or any warning messages were produced. You then can check the ERROR-STATUS handle for the specific messages.

**V6FRAME** `[ = logical-expression ] [ USE-REVVIDEO | USE-UNDERLINE ]`

The V6FRAME option is designed specifically to compile and run Progress Version 6 applications with Progress Version 7 or later in Windows. This option uses the V6FontNumber setting in the [Startup] section of the current environment (which might be the Registry or an initialization file) to calculate the height and width of a character unit and then set the layout grid used to compile frames for display in Progress Version 7 or later.

At run time, the FONT attribute for a frame compiled with the V6FRAME option is set to the font number specified with the V6FontNumber setting. The default setting for the V6FontNumber setting is 3.

By default, V6FRAME displays a border around a fill-in field. This means that your code requires more space on the screen than in Progress Version 6. You can override this behavior with one of the following options:

- **USE-REVVIDEO** displays no border around a fill-in field. When a fill-in is enabled for input, the color of the fill-in changes to the color specified with the INPUT setting.
in the [Colors] section in the current environment (which might be the registry or an initialization file). The IBEAM cursor signals that a fill-in field has input focus.

• **USE-UNDERLINE** displays no border around a fill-in widget. When a fill-in is enabled for input, the underline attribute of the font (V6FontNumber) for the fill-in is turned on. The color of a fill-in enabled for input does not change. The IBEAM cursor signals that a fill-in field has input focus.

The V6FRAME option also limits the vertical size of a frame title to one character unit based upon the layout grid. The text of the frame title is in the font specified with the V6FontNumber setting in the [Startup] section of the current environment (which might be the registry or an initialization file).

The V6FRAME option governs the appearance of screen output only. Use the STREAM-IO option to compile procedures that output to files and printers. If you specify the V6FRAME and STREAM-IO options in the same COMPILE statement, the STREAM-IO option overrides the V6FRAME option.

If you specify a `logical-expression`, its value determines whether the V6 compile option is activated. If the `logical-expression` is evaluated to the Unknown value (?), a run-time error occurs.

For more information on the environment for an ABL session, see *OpenEdge Deployment: Managing ABL Applications*.

**MIN-SIZE** `[ = logical-expression ]`

Minimizes the size of the generated r-code file by eliminating the Debugger Segment (which is used by the OpenEdge Debugger) and the signature descriptor data (which is used by the Open Client Proxy Generator).

If you specify a `logical-expression`, its value determines whether the MIN-SIZE option is activated (TRUE) or not (FALSE). If the `logical-expression` evaluates to the Unknown value (?), a run-time error occurs. The default value is FALSE.

**GENERATE-MD5** `[ = logical-expression ]`

When ABL compiles a procedure or class definition file with the GENERATE-MD5 option, it generates a special MD5 value based on the code content, and stores it in the r-code file. This r-code MD5 value is similar to a CRC value, except the MD5 value is 128 bits in size and the CRC value is only 16 bits. The MD5 value is virtually guaranteed to be different if the file content has changed. As with CRC, content changes include any schema changes. That is, if only the schema changes, the MD5 value also changes.

If you specify a `logical-expression`, its value determines whether the GENERATE-MD5 option is activated (TRUE) or not (FALSE). The default value is TRUE.

You can read the **MD5-VALUE attribute** on the RCODE-INFO system handle to determine the MD5 value for a procedure or class.

This option is supported for WebClient™ only (that is, only WebClient uses the resulting MD5 value). Progress Software Corporation recommends compiling your WebClient application procedures with this option. Using this option lets WebClient determine if an r-code file has changed since the previous version of the application.
In this procedure, ABL compiles the `ord-ent` procedure, produces an r-code file, `ord-ent.r`, that can be used across ABL sessions, and saves the r-code file in the current directory:

```plaintext
r-comple.p

COMPILE ord-ent SAVE.
```

**Note:** The sample procedures supplied with ABL do not include the `ord-ent` procedure.

You can save the r-code file in a different directory by using the `SAVE INTO` phrase. For example, to save an r-code file in `/usr/sources` on a UNIX system, enter this command:

```plaintext
COMPILE ord-ent SAVE INTO /usr/sources.
```

The following example shows the effect of include files on compilation listings:

```plaintext
r-incl.p

FOR EACH Customer NO-LOCK:
    {r-fcust.i}
    {r-dcust.i}
END.
```

Suppose you use the following `COMPILE` statement to compile the `r-incl.p` procedure:

```plaintext
r-comlis.p

COMPILE r-incl.p SAVE LISTING r-incl.lis XREF r-incl.xrf
    DEBUG-LIST r-incl.dbg.
```

This `COMPILE` statement produces four files: `r-incl.r`, `r-incl.lis`, `r-incl.xrf`, and `r-incl.dbg`.

The following procedures contain the contents of the `r-incl.lis`, `r-incl.xrf`, and `r-incl.dbg` files:
This sample output is not an exact copy of the r-incl.lis file.

There are three columns next to the procedure in the listing file:

1. {} — The level of the include file
2. Line — The line number in the file
3. Blk — The number of the block

The information follows each of the procedure blocks or function blocks:

- **Line** — The line number where the block starts
- **Blk. Type** — The type of block (Procedure, DO, FOR EACH, REPEAT)
- **Tran** — Whether the block is a transaction block
- **Blk. Label** — The label of the block
- **Buffers** — The name of the record buffer scoped to the block
- **Frames** — The name of the frame scoped to the block

This is the cross-reference file r-incl.xrft
Each line in the xref file specifies the procedure, line number, access type, and access information. The first line in the xref file contains the COMPILE access type directive and the name of the procedure exactly as it appears in the COMPILE statement. See Table 16 for a list of the values that follow a particular access type (for example, table and index after SEARCH).

If you modified r-comlis.p to use the XREF-XML option instead of XREF, your cross reference file would be named r-comlis.xref.xml. The structured formatting of XML would use many more lines to display the same information on one line of standard XREF output. Here is a small snippet of that file:

```plaintext
r-incl.xrf

r-incl.p r-incl.p 1 COMPILE r-incl.p
r-incl.p r-incl.p 3 STRING "Customer" 8 NONE UNTRANSLATABLE
r-incl.p r-incl.p 3 SEARCH sports2000.Customer CustNum
r-incl.p r-incl.p 4 INCLUDE r-fcust.i
r-incl.p r-fcust.i 3 ACCESS sports2000.Customer CustNum
r-incl.p r-fcust.i 3 ACCESS sports2000.Customer Name
r-incl.p r-fcust.i 3 ACCESS sports2000.Customer Phone
r-incl.p r-fcust.i 3 STRING ">>>>9" 5 NONE TRANSLATABLE FORMAT
r-incl.p r-fcust.i 3 STRING "x(20)" 5 NONE TRANSLATABLE FORMAT
r-incl.p r-fcust.i 3 STRING "999-999-9999" 12 NONE TRANSLATABLE FORMAT
r-incl.p r-incl.p 5 INCLUDE r-dcust.i
r-incl.p r-dcust.i 3 ACCESS sports2000.Customer CustNum
r-incl.p r-dcust.i 3 ACCESS sports2000.Customer Name
r-incl.p r-dcust.i 3 ACCESS sports2000.Customer Phone
r-incl.p r-incl.p 6 STRING "CustNum" 8 LEFT TRANSLATABLE
r-incl.p r-incl.p 6 STRING "Customer Name" 13 LEFT TRANSLATABLE
r-incl.p r-incl.p 6 STRING "Phone" 5 LEFT TRANSLATABLE
"-------- ---------------------- --------------" 46 LEFT TRANSLATABLE
r-incl.p r-incl.p 6 STRING "CustNum" 8 LEFT TRANSLATABLE
```
This is the debug listing `r-incl.dbg`:
Notes

• When compiling class definition files, the following options apply to the class definition file identified in the COMPILE statement and all class files in its inherited class hierarchy: XCODE, STREAM-IO, LANGUAGES, V6FRAME, MIN-SIZE and GENERATE-MD5.

• When compiling class definition files, the following options apply only to the class definition file identified in the COMPILE statement, and not to the class files in its inherited class hierarchy: PREPROCESS, LISTING, DEBUG-LIST, XREF, and STRING-XREF.

• If you want all record retrieval statements in a procedure to default to NO-LOCK, you must compile the procedure in an ABL session started with the No Lock (−NL) startup parameter. For more information on record locking, see OpenEdge Getting Started: ABL Essentials. For more information on the No Lock (−NL) startup parameter, see OpenEdge Deployment: Startup Command and Parameter Reference.

• Two additional startup parameters are available that can affect the behavior of the COMPILE statement: Compile Warning List (−cwl) and Keyword Forget List (−k). The Compile Warning List option lets you specify a set of ABL statements that trigger compile-time warnings if they are found in the source code. The Keyword Forget List option lets you disable specified keywords, allowing you to compile code in which those keywords occur as ABL user-defined element names, such as table, field, variable, and procedure names. For more information about these startup parameters, see OpenEdge Deployment: Startup Command and Parameter Reference.

• The value of the PROPATH environment variable defines the list of directories (path) to use when searching for a procedure.

• The ABL compiler does not search procedure libraries for include files referenced in a procedure.

• On UNIX, you define the PROPATH variable in a startup script or in your .profile file. In Windows, you can define your PROPATH in the Registry or in an initialization file. You can also define the PROPATH interactively at the operating system level.

In addition to any directories you define for PROPATH, ABL searches the directory containing the ABL system software. If you do not define a value for PROPATH, ABL searches your working directory by default.
• To locate the source file that you name in the COMPILE SAVE statement, ABL searches the first directory in PROPATH. If the source file is there, ABL compiles the source file and creates an r-code file. On UNIX, this new r-code file replaces any existing r-code file. If errors occur during compilation, ABL does not produce an r-code file and leaves existing r-code files unchanged.

If ABL cannot find the source file, it continues on to the next directory in PROPATH.

• Use the SAVE INTO phrase to store a compiled r-code file in a different directory from its corresponding source file.

If you specify a relative pathname for the source file, that pathname is appended to the SAVE INTO path. For example (using UNIX pathnames):

```
PROPATH="/pro1/source".
COMPILE test/proc1.p SAVE INTO /pro1/obj.
```

In the example, ABL saves the source file `/pro1/source/test/proc1.p` as `/pro1/obj/test/proc1.r`.

If the source file is a full pathname, ABL stores the r-code file in the SAVE INTO directory; it drops its original directory path. For example:

```
COMPILE /pro1/obj/test/proc1.p SAVE INTO /usr/rcode.
```

In the example, ABL saves the source file as `/usr/rcode/proc1.r`.

When you use the SAVE INTO phrase to store compiled r-code files for one or more class definition files specified with a package, ABL creates a directory structure under the specified SAVE INTO directory that is consistent with the directory structure of the original source files relative to PROPATH (if the directory structure doesn’t already exist). That is, ABL creates a subdirectory under the specified SAVE INTO directory to match the original source directory for each class definition file in the hierarchy.

For example, if the source for two class definition files in a class hierarchy reside in two different directories, such as `dir1` and `dir2`, ABL creates two matching subdirectories named `dir1` and `dir2` under the specified SAVE INTO directory and stores the r-code files in their respective subdirectories.

If the SAVE INTO pathname is null, ABL saves r-code files in the same directory as their source files.

• The ATTR-SPACE/NO-ATTR-SPACE designation in a Frame phrase takes precedence over an ATTR-SPACE/NO-ATTR-SPACE designation in a Format phrase. The ATTR-SPACE/NO-ATTR-SPACE designation in a Format phrase takes precedence over an ATTR-SPACE/NO-ATTR-SPACE designation in a COMPILE statement.

• To locate a file with the COMPILE statement (without the SAVE phrase), ABL searches the first directory in PROPATH for a usable r-code file. A usable r-code file must meet these criteria:
– It must have the correct format; it must have been produced by the COMPILE SAVE statement.

– It must have been produced by the current version of the ABL compiler.

– It must have the same cyclic redundancy check (CRC) value as any database tables it references, or the same time stamp if you are running with the Timestamp (-tstamp) parameter. When creating an r-code file, ABL includes, as part of the r-code file, either the CRC or the time stamp of the most recent change to the database schema that affects this procedure (for example, adding or deleting a field or index definition in a table that the procedure references).

– On UNIX, it must have read access to the r-code file.

If there is a usable r-code file, there is no reason to perform the compilation. You receive an error and the compilation stops unless you have specified the XREF, LISTING, PREPROCESS, or DEBUG-LIST option. If you specified one of these options, ABL continues with the compilation and produces the files specified and a session compile. If ABL does create a session compile version, the version is not used when you use the RUN statement. The RUN statement always uses an existing r-code file before using a session compile version of a procedure.

If there is no usable r-code file, ABL searches the same directory in PROPATH for a source file. If the source file is there, ABL compiles it into the session compile file. If it is not there, ABL continues on to the next directory in PROPATH, searching for an r-code file, then for a source file.

• After you compile a procedure, the RUN statement does not recompile it. If you RUN a procedure multiple times within a session, changing the procedure between runs, you must manually recompile the procedure each time. Otherwise, the procedure's last r-code, which persists for a session, is found and the procedure is not automatically recompiled.

• The size of the r-code might vary, depending on the window system on which it is compiled.

• Modifications to existing field definitions do not affect database table CRC or time-stamp values. Therefore, updating a table's existing field definitions does not invalidate r-code versions of procedures that reference the table. However, adding or deleting tables, fields, or indexes does affect database table CRC and time stamps. This invalidates r-code versions of procedures that reference the changed tables.

• When you use a reserved keyword to specify a language with the LANGUAGES option, you must use quotation marks (" ") around the language-list.

• The SORT-BY-EXP reference in the XREF is used to indicate a FOR EACH or OPEN QUERY statement which contains a BY clause which uses an expression.

• A WHOLE-INDEX search reported for a table occurs when an entire index is used to search the table. (That is, the bracket used by the query to search the table spans the entire index.) This can occur either when no selection criteria are specified to limit the range of index keys searched (that is, to bracket a subset of the index) or when there is no appropriate index available to optimize the selection criteria. For example, the following queries on Customer table of the sports2000 database both result in WHOLE-INDEX searches. The first query uses the Name index to search the entire table, returning every
record in Name order. The second query uses the primary index to search the entire table because there is no index provided for the Balance field to limit the search.

```
FOR EACH Customer NO-LOCK USE-INDEX Name:
    DISPLAY Customer.
END.

FOR EACH Customer NO-LOCK WHERE Customer.Balance < 10000
    AND Customer.Balance > 5000:
    DISPLAY Customer.
END.
```

On the other hand, the following queries do not result in WHOLE-INDEX searches because the selection criteria directly limit the range of Name and CustNum index keys (respectively) to be searched:

```
FOR EACH Customer NO-LOCK
    WHERE Customer.Name < "Penan Sporttklubi"
        AND Customer.Name > "Chip's Poker":
    DISPLAY Customer.
END.

FOR EACH Customer NO-LOCK WHERE Customer.CustNum < 40:
    DISPLAY Customer.
END.
```

- For SpeedScript, the following options are invalid: V6FRAME, USE-REVVIDEO, and USE-UNDERLINE.

See also COMPILER system handle, NEW function (classes), RUN statement, Compile Warning List (-cwl), Keyword Forget List (-k), and No Lock (-NL) startup parameters (in OpenEdge Deployment: Startup Command and Parameter Reference)

**CONNECT statement**

Allows access to one or more databases from within an ABL procedure.

**Syntax**

```
CONNECT
{
    { physical-name | VALUE ( expression ) } [ options ] | options
}
[ NO-ERROR ]
```

**physical-name**

The actual name of the database on disk. It can be a simple filename, relative pathname, or a fully qualified pathname, represented as an unquoted string, or a quoted string. If you do not give a fully qualified pathname, the AVM searches for the database relative to your current working directory.
An expression (a constant, field name, variable name, or other expression) whose value is a character string starting with the Physical Database Name (-db) startup parameter and followed by zero or more of the same client startup parameters that you can specify in options.

options

One or more client startup parameters, similar to those used to start OpenEdge. Valid options are a subset of OpenEdge startup parameters that include all client database connection parameters. If you specify options without physical-name or VALUE (expression), the first database connection parameter must be the Physical Database Name (-db) startup parameter. Note that these parameters are case sensitive.

For more information on client database connection parameters, see OpenEdge Deployment: Startup Command and Parameter Reference.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

For the CONNECT statement with NO-ERROR, the option does not suppress all errors produced by the server; only errors caused by the CONNECT statement itself. For example, if the server to which you are connecting runs out of resources, its error message will not be suppressed. If a CONNECT error occurs (for example, the database does not exist or is in use in single-user mode), error information is written to the ERROR-STATUS system handle.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.
Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

Examples

This procedure attempts to connect to databases mydb1 and mydb2 in single-user mode, with error suppression. You must connect to a database before you run a procedure that references it.

r-connct.p

```
CONNECT mydb1 -1 -db mydb2 -1 NO-ERROR.
```

The following four code fragments attempt exactly the same database connection to the Sports2000 database:

```
CONNECT C:\OpenEdge\WRK\db\Sports2000 -H dbserver -S 1900 NO-ERROR.
```

```
CONNECT -db C:\OpenEdge\WRK\db\Sports2000 -H dbserver -S 1900 NO-ERROR.
```

```
CONNECT VALUE("-db C:\OpenEdge\WRK\db\Sports2000 -H dbserver -S 1900") NO-ERROR.
```

```
CONNECT VALUE("-db C:\OpenEdge\WRK\db\Sports2000 -H dbserver") -S 1900 NO-ERROR.
```
In the next example, assume database sports2000 has not been previously connected, so the following r-cnct1.p procedure fails. At the start of execution, r-cnct1.p checks whether sports2000 is connected. If sports2000 is not connected, a run-time error occurs. As shown in the example, attempting to connect to sports2000 within the procedure does not solve the problem:

```/* NOTE: this code does NOT work */
CONNECT sports2000 -1.
FOR EACH sports2000.Customer NO-LOCK:
    DISPLAY Customer.
END.
```

Instead, split r-cnct1.p into two procedures, as shown in r-dispcu.p and r-cnct2.p:

**r-dispcu.p**

```FOR EACH sports2000.Customer NO-LOCK:
    DISPLAY Customer.
END.
```

**r-cnct2.p**

```CONNECT sports2000 -1.
RUN r-dispcu.p.
```

This time, database sports2000 is connected before r-dispcu.p is invoked, so r-dispcu.p runs successfully.

### Notes

- Each connected database is assigned a logical name for the current session, and is referred to by this logical name during the session. Use the Logical Database Name (-ld) parameter to specify a logical name. If the logical name is not specified using the -ld parameter, then the physical database filename, without the .db suffix, is the default logical name. For example, if the physical name is /users/eastcoast/proapp/mydb.db, then the default logical name is mydb. Logical names are **not** case sensitive.

- Databases can have aliases (see also ALIAS function). A database can have more than one alias, but each alias refers to only one database. The first database connected during a given session automatically receives the alias DICTDB. The first database connected that has a _menu file automatically receives the alias FTDB. You can reassign the FTDB alias to any other FAST TRACK database.

- When you try to connect the same database twice using the same logical name, the AVM returns a warning, which you can suppress with NO-ERROR.

- When you try to connect different databases using the same logical name, the AVM returns an error message and an error condition. You can suppress the error condition with NO-ERROR, and test with the CONNECTED function.

- When you try to connect to multiple databases and a connection fails, a run-time error occurs. The successfully connected databases remain connected and program execution continues. Use the CONNECTED function to find out which databases are successfully connected.
• If you run a procedure that requires a database and that database is not connected, the AVM searches for the database in the auto-connect lists in all connected databases. If the AVM finds the required database there, it automatically attempts to connect to the database with the parameters set for it in the auto-connect list. You can edit the auto-connect list using the database utilities in the OpenEdge Data Dictionary. If the AVM does not find it, the connection attempt fails.

• Connection information found in an OpenEdge auto-connect list is merged with connection information in a CONNECT statement that connects the database. So, if you connect a database with a CONNECT statement, and that database already has an entry in the OpenEdge auto-connect list of a connected database, the connection information in the auto-connect list and the CONNECT statement is merged. However, the connection information in the CONNECT statement takes precedence.

• Permission issues limit the use of the CONNECT statement for raw I/O connections to databases in single-user and multi-user direct-access mode on UNIX machines that do not support O_SYNC and SWRITE.

At startup, the ABL client executable has superuser privileges that allow it to open raw disk devices. Thus, you can open any databases specified on the startup command line with raw I/O. After startup, the client executable relinquishes the superuser privileges that allow it to open raw disk devices. As a result, you cannot use the CONNECT statement to establish a raw I/O connection to a database in single-user or multi-user direct-access mode.

When you try to use a CONNECT statement to open a raw I/O connection to a database in single-user mode, the AVM establishes a buffered (non-raw) I/O connection to the database and displays a non-raw warning message.

• When you try to use a CONNECT statement to open a raw I/O connection to a database in multi-user direct-access mode, one of the following events occur:
  – If you started a server (PROSERVE) for the database with the Buffered I/O (-r) parameter, the AVM establishes a non-raw I/O connection to the database.
  – If you started a server (PROSERVE) for the database with the Raw I/O (-R) parameter, the CONNECT statement fails.

There are several ways to avoid these problems:
  – Establish raw I/O database connections in the single-user and multi-user direct-access modes at ABL startup.
  – If you must use the CONNECT statement to establish a raw I/O database connection, establish the connection with the Client Multi-user (-cl) parameter. Be sure to start the database server (PROSERVE) with the Raw I/O (-R) parameter before you do this.
  – If you must use the CONNECT statement to establish a raw I/O database connection in single-user or multi-user direct access mode on UNIX, follow these steps carefully:
    1. Change the permissions of the ABL client executable to rwsrwsr-x by typing `chmod 6775 _progres`.  
2. Change the group of the client executable to match the group of the raw device (for example, /dev/rsd0d) and block special device (for example, /dev/sd0d).

3. Change the permissions of the raw and block special devices to "rw-rw----".

The disadvantage of this procedure is that all files produced within OpenEdge have the same group as the disk device. Consider the following:

– If you want to run a multi-user direct-access session in non-raw mode, you must start the database server with the Buffered I/O (-r) parameter.

– If a database and accompanying before-image file have read-only permissions (r--r--r--) and you try to connect to that database in single-user or multi-user mode using the CONNECT statement, the connection will fail with the following error:

```
errno=13
```

This connection failure results because the _progres module relinquishes superuser privileges after start-up and no longer possesses the privileges required to connect to the database using the CONNECT statement.

- For more information on connecting to databases, see *OpenEdge Development: Programming Interfaces*.

### CONNECTED function

Tells whether a database is connected. If *logical name* is the logical name or *alias* is the alias of a connected database, the CONNECTED function returns TRUE; otherwise, it returns FALSE.

#### Syntax

```
CONNECTED ( logical-name | alias )
```

*logical-name*

Refers to a logical name. It can be a quoted string or a character expression. An unquoted character string is not allowed.

*alias*

Refers to an alias. It can be a quoted string or a character expression. An unquoted character string is not allowed.

#### Example

This procedure runs `r-dispcu.p` if a database with the logical name `sports2000` is connected:
CONSTRUCTOR statement

**CONSTRUCTOR statement**

Defines a constructor for a class. A constructor is a special type of method that ABL invokes to initialize data for a new object of a class that is instantiated using the `NEW function (classes)`, `NEW statement`, or `DYNAMIC-NEW statement`, or to initialize static members of a class.

**Note:** This statement is applicable only when used in a class definition (.cls) file.

**Syntax**

```
CONSTRUCTOR [ PRIVATE | PROTECTED | PUBLIC | STATIC ] class-name
( [ parameter [ , parameter ] ... ] ) :
constructor-body
```

[ PRIVATE | PROTECTED | PUBLIC | STATIC ]

Specifies the access mode for the constructor.

PRIVATE specifies an instance constructor that you can call explicitly within another constructor of the defining class (using the `THIS-OBJECT statement`) during class instantiation, or that a static method or static constructor of the class can invoke by executing the `NEW function (classes)` in order to allow the class to instantiate itself.

PROTECTED specifies an instance constructor that you can only call explicitly within a constructor of an immediately inheriting subclass (using the `SUPER statement`) during class instantiation.

PUBLIC specifies an instance constructor that you can call explicitly from within another constructor in the defining class during class instantiation, that you can call explicitly from within a constructor of an immediately inheriting subclass during class instantiation, and that you can call implicitly from any class or procedure when you instantiate the class.

STATIC specifies a static constructor that executes exactly once in an ABL session the first time you reference a class type that defines this constructor in its class hierarchy. You cannot invoke a static constructor in any other way or at any other time. You can define only one static constructor for a given class. If you do not define a static constructor, ABL defines a default static constructor to initialize the static members of a class.

The default access mode is PUBLIC.
**CONSTRUCTOR statement**

*class-name*

The name of the class this method constructs. This name must match the class name portion of the type name for the class (that is, the name of the class definition file excluding the .cls extension and any package path information).

(` parameter , parameter ... `)

Optionally specifies one or more parameters of the constructor. Any instance constructor defined without a parameter list is the default instance constructor for the defining class. The parameter list for a defined static constructor must be empty.

If this instance constructor is one of several overloaded constructors defined for a class, the parameter list must be unique among all the other constructors. This uniqueness can be established using a different combination of number, data types, or modes for the parameters. For information on the parameter definition syntax and establishing uniqueness for overloaded constructors, see the Parameter definition syntax reference entry. Note that any defined static constructor does not participate in constructor overloading with instance constructors.

*constructor-body*

The body of the constructor definition. Define the constructor body using the following syntax:

**Syntax**

```
constructor-logic
  . . .
END [ CONSTRUCTOR ].
```

*constructor-logic*

The logic of the constructor, which can contain any ABL statements currently allowed within a PROCEDURE block including class-related statements. These statements typically contain logic to initialize the data members and properties in the class.

Each logic statement must end with a period.

If you are defining an instance constructor, regardless of other statements in the constructor, the first action of the constructor must be a call to another instance constructor in the defining class or in the immediate super class. ABL can call a default super class constructor implicitly, or you can call a super class constructor or another overloaded constructor in the defining class explicitly as the first statement of a constructor. You cannot explicitly call another constructor in any other statement of a constructor, and you cannot call any defined static constructor.

If there is no constructor instance defined in the immediate super class and you do not explicitly invoke a constructor, ABL always implicitly invokes the built-in default super class constructor (without parameters) as the first action. If there is an instance constructor defined in the super class that does not take parameters, you also do not need to explicitly invoke an instance constructor. ABL implicitly invokes this user-defined default super class constructor. You only need to explicitly invoke
another instance constructor when the super class has constructors defined for it and all of these constructors take parameters.

When you invoke an instance constructor that takes parameters, again, you must invoke that constructor as the first executable statement in the invoking constructor. If you want to invoke a super class instance constructor, you must invoke the SUPER statement with parameters that match the parameters of the super class constructor with respect to number, data type, and mode.

If you want to invoke an overloaded instance constructor of the defining class, you must invoke the THIS-OBJECT statement as the first statement, with parameters that match the parameters of the overloaded constructor with respect to number, data type, and mode. If you invoke an overloaded constructor, and that overloaded constructor does not invoke another overloaded constructor, it must invoke a super class constructor, either implicitly (the default) or explicitly as its first statement. So, in any chain of explicit calls from one overloaded constructor to another, the last overloaded constructor in the chain must invoke a super class constructor.

If you are defining a static constructor, you cannot access any instance members of a class (including the defining class), nor can you use the SUPER and THIS-OBJECT statements. From a static constructor, you can access only other static members of a class and the local variables or other local data elements of the constructor. A static constructor also cannot execute any input-blocking statements, such as UPDATE or WAIT-FOR.

END [ CONSTRUCTOR ]

Specifies the end of the constructor body definition. You must end the constructor body definition with the END statement.

Examples

The following example shows the definition of an instance constructor:

```constr
CONSTRUCTOR PUBLIC CustObj( ):
  m_NumCusts = 0.

  /* Fill a temp table and get the row count */
  FOR EACH Customer NO-LOCK:
    CREATE ttCust.
    ASSIGN
      ttCust.CustNum = Customer.CustNum
      ttCust.Name   = Customer.Name
    m_NumCusts = m_NumCusts + 1.
END.

END CONSTRUCTOR.
```

For more examples of constructor definitions, including a static constructor and a constructor for an abstract class, see the descriptions of `r-CustObj.cls`, `r-CustObjStatic.cls`, and `r-CustObjAbstract.cls` in the CLASS statement reference entry.

Notes

- You can terminate a CONSTRUCTOR statement with either a period (.) or a colon (:), but typically use a colon (:).
- A constructor definition must begin with the CONSTRUCTOR statement and end with the END statement.
CONSTRUCTOR statement

- A constructor has no return type.

- You never explicitly invoke an instance constructor to create a class instance. The constructor is implicitly invoked when you instantiate the defining class using the NEW function (classes), NEW statement, or DYNAMIC-NEW statement, passing any parameters required to identify the instantiating constructor. The instantiating constructor then directly or indirectly calls an instance constructor in its immediate super class, which similarly calls an instance constructor in its immediate super class, and so on for all classes in the class hierarchy, until the default instance constructor of the root (Progress.Lang.Object class) is called. From this point, the root constructor and all previously called instance constructors complete execution in reverse order of invocation, terminating class instantiation with completion of the initial instantiating constructor.

- Within a class hierarchy, you can explicitly invoke an instance constructor from an instance constructor of an immediate subclass using the SUPER statement or from an overloaded constructor in the same defining class using the THIS-OBJECT statement. The invoking constructor must specify any parameters required to identify the called constructor. These parameters must match the constructor parameters with respect to the number, data type, and mode.

- You never explicitly invoke a static constructor. All the static constructors of a class hierarchy with static members execute on first reference to a given class within an ABL session. This first reference causes the static constructors of all super classes in the referenced class hierarchy that have static members to execute from top to bottom, terminating with the execution of the static constructor for the most derived class with static members. For any single class with static members, its static constructor runs only once per ABL session or until after the given class is compiled again. If the first reference to a class occurs during class instantiation, this sequence of static constructor execution occurs prior to execution of the instantiating constructor. Thus, all static constructors in a class hierarchy are guaranteed to execute before a class instance is referenced.

- Prior to execution of a given static constructor, all of the static data members and properties of the defining class are set to their initial values. The constructor then accesses these initial values of static members, as appropriate. This initialization of static members occurs only once per session or until the class is recompiled.

- You can handle application errors in an instance constructor as in any ABL block. However, by executing a RETURN ERROR action at the block level or a THROW action at the block level with the presence of a ROUTINE-LEVEL ON ERROR UNDO, THROW statement, the AVM returns the ERROR condition from the constructor block. With this returned ERROR condition, ABL terminates creation of the object. If any part of the class hierarchy has been created (constructors executed), ABL executes the corresponding destructors for those classes automatically and raises ERROR on the statement that instantiated the class. If this constructor is invoked as part of a NEW statement or DYNAMIC-NEW statement, the data element set to receive an object reference to the failed class instantiation remains unchanged. If a RETURN ERROR also includes the option to return a character string value, or you set the ReturnValue property of a Progress.Lang.AppError object that you THROW, you can get this value using the RETURN-VALUE function following the statement that attempted to instantiate the class or in a CATCH block that catches the Progress.Lang.AppError object. For more information, see OpenEdge Development: Object-oriented Programming.

- You can handle application errors in a static constructor similar to an instance constructor. However, an ERROR condition returned from the constructor block is raised on the
COPY-LOB statement

A statement whose class reference caused the static constructor to be invoked (whether or not the statement instantiates the class). With this ERROR condition, ABL fails to load the specified class and its entire class hierarchy. In addition, ABL does not load the specified class, or the other classes of its class hierarchy, for the remainder of the ABL session, or until the specified class is recompiled.

COPY-LOB statement

Copies large object data between BLOBs, CLOBs, MEMPTRs, and LONGCHARs. It also copies large object data to and from the file system, and converts large object data to or from a specified code page.

Note: You cannot copy large object data between BLOBs and CLOBs directly. However, you can copy a BLOB or CLOB to a MEMPTR or LONGCHAR (which converts the data) and then copy the MEMPTR or LONGCHAR to the CLOB or BLOB, respectively.

Syntax

```
COPY-LOB
  [ FROM ] { [ OBJECT ] source-lob | FILE source-filename } [ STARTING AT n ] [ FOR length ]
  [ NO-CONVERT | CONVERT convert-phrase ] [ NO-ERROR ].
```

[ OBJECT ] source-lob

The source object to be copied, which can be a MEMPTR or LONGCHAR variable, a BLOB or CLOB database or temp-table field, or a dynamic expression that resolves to a BLOB or CLOB database or temp-table field. The source object data at this location is copied to the specified target object or file.

FILE source-filename

A character expression that specifies the name of a file containing the source object data to be copied. The object data in this source file is copied to the specified target object or file. You can specify an absolute or relative pathname. Any relative pathname is relative to the current working directory.

The AVM raises the ERROR condition if source-filename resolves to the Unknown value (?) or the source file cannot be read.

STARTING AT n

An integer expression indicating a one-based offset position, in the source object or file, from which to start copying. The copy begins at offset 1, by default. The AVM raises the
ERROR condition if the specified offset position is less than 1, greater than the size of the object or file, or the Unknown value (?).

**Note:** Offsets are measured in bytes for binary data (BLOB or MEMPTR), and characters for character data (CLOB or LONGCHAR).

**FOR** *length*

An integer expression indicating the number of bytes or characters to copy from the source object or file starting at the specified offset position. The AVM copies from the specified offset position to the end of the object or file, by default. The AVM raises the ERROR condition if the specified length is less than 0, greater than the size of the object or file, or the Unknown value (?).

**Note:** Offsets are measured in bytes for binary data (BLOB or MEMPTR), and characters for character data (CLOB or LONGCHAR).

**[ OBJECT ]** *target-lob*

The target object to receive the copy, which can be a MEMPTR or LONGCHAR variable, a BLOB or CLOB database or temp-table field, or a dynamic expression that resolves to a BLOB or CLOB database or temp-table field. The object data in the specified source object or file is copied to the target object.

If the specified target object does not yet exist, the AVM either creates a BLOB or a CLOB, or allocates memory for a MEMPTR or a LONGCHAR. If the specified target object already exists, the AVM deletes the object before the copy operation begins, by default. You can specify the **OVERLAY AT n** option to overlay some portion of an existing target object.

**Note:** Although the AVM allocates memory for a target MEMPTR, you are responsible for freeing that memory.

**OVERLAY AT n [ TRIM ]**

An overlay position in the target object. The AVM copies the source object or file to an existing BLOB, CLOB, MEMPTR, or LONGCHAR target starting at the given position. If the operation results in writing past the end of a target BLOB, CLOB, or LONGCHAR, the AVM extends the target object as necessary. If the operation results in writing past the end of a target MEMPTR, the AVM raises the ERROR condition.

If the target object does not yet exist, the AVM raises the ERROR condition. If the specified overlay position is less than 1, greater than the size of the object, or the Unknown value (?), the AVM raises the ERROR condition.

You can specify the **TRIM** option only if the target object is a BLOB or CLOB. In this case, the AVM copies the source object or file to the existing target object and truncates any data remaining in the target object. If the target object is a MEMPTR or LONGCHAR, the AVM ignores this option.
COPY-LOB statement

FILE target-filename [ APPEND ]

A character expression that specifies the name of the target file to which the object data in the specified source object or file is copied. You can specify an absolute or relative pathname. Any relative pathname is relative to the current working directory.

If the target file does not exist, the AVM creates the file. If the target file exists, and you specify the APPEND option, the AVM opens the file and appends the object data to the end of a file. If the target file exists, but you do not specify the APPEND option, the AVM creates the target file anew (which overwrites the original file).

If target-filename resolves to the Unknown value (?), or the target file cannot be created or written, the AVM raises the ERROR condition.

NO-CONVERT | CONVERT convert-phrase

Lets you specify the character conversion behavior between the source and target objects.

The NO-CONVERT option specifies that no conversions occur. However, if the target is a LONGCHAR or a CLOB, the AVM validates the character data based on the target object’s code page. For a CLOB, this is the code page of the CLOB. For a LONGCHAR, this is -cpinternal unless the LONGCHAR’s code page was set using the FIX-CODEPAGE statement. If the validation fails, the AVM raises the ERROR condition.

The CONVERT option lets you specify how the AVM converts object data. Following is the syntax for convert-phrase:

Syntax

{ [ SOURCE CODEPAGE codepage ] [ TARGET CODEPAGE codepage ] }

Specify SOURCE CODEPAGE to indicate that a source object is in the specified code page. If you specify TARGET CODEPAGE, the AVM converts the target object to the specified code page.

Table 18 lists the default character conversions the AVM performs when copying data between the source and target objects. References to CLOBCP and CLOBDB represent CLOB data in either the CLOB’s defined code page or the database’s defined code page, respectively. References to the "fixed code page" represent the code page of a target LONGCHAR variable set using the FIX-CODEPAGE statement.
### Table 18: Default COPY-LOB statement character conversions

<table>
<thead>
<tr>
<th>When the source object is a . . .</th>
<th>And the target object is a . . .</th>
<th>The AVM converts the source object . . .</th>
</tr>
</thead>
<tbody>
<tr>
<td>MEMPTR</td>
<td>LONGCHAR</td>
<td>From <code>-cpinternal</code> to <code>-cpinternal</code> or the fixed code page</td>
</tr>
<tr>
<td>MEMPTR</td>
<td>CLOBDB</td>
<td>From <code>-cpinternal</code> to the database's defined code page</td>
</tr>
<tr>
<td>MEMPTR</td>
<td>CLOBCP</td>
<td>From <code>-cpinternal</code> to the CLOB’s defined code page</td>
</tr>
<tr>
<td>BLOB</td>
<td>LONGCHAR</td>
<td>No conversion, the LONGCHAR is in <code>-cpinternal</code> or the fixed code page</td>
</tr>
<tr>
<td>LONGCHAR</td>
<td>MEMPTR</td>
<td>From the LONGCHAR’s code page to <code>-cpinternal</code></td>
</tr>
<tr>
<td>LONGCHAR</td>
<td>BLOB</td>
<td>No conversion, the BLOB’s code page is unknown</td>
</tr>
<tr>
<td>LONGCHAR</td>
<td>CLOBDB</td>
<td>From the LONGCHAR’s code page to the database's defined code page</td>
</tr>
<tr>
<td>LONGCHAR</td>
<td>CLOBCP</td>
<td>From the LONGCHAR’s code page to the CLOB’s defined code page</td>
</tr>
<tr>
<td>CLOBDB</td>
<td>MEMPTR</td>
<td>From the database's defined code page to <code>-cpinternal</code></td>
</tr>
<tr>
<td>CLOBDB</td>
<td>LONGCHAR</td>
<td>From the database's defined code page to <code>-cpinternal</code> or the fixed code page</td>
</tr>
<tr>
<td>CLOBCP</td>
<td>MEMPTR</td>
<td>From the CLOB’s defined code page to <code>-cpinternal</code></td>
</tr>
<tr>
<td>CLOBCP</td>
<td>LONGCHAR</td>
<td>No conversion, or conversion to the fixed code page</td>
</tr>
</tbody>
</table>

**Note:** If either the source or target object is a file, the target’s code page defaults to `-cpstream`.

### NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the **ERROR-STATUS** system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the **NO-ERROR** option:
• Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

• Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

• Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

• NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

• A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

• When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

• If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

Notes

• If a source or target object is stored in a database, its record must be available to copy. The lock mode of the record containing the target object must be EXCLUSIVE-LOCK or SHARE-LOCK and upgradeable; otherwise, the COPY-LOB statement raises the ERROR condition.

• You can also assign large object data from one BLOB or MEMPTR to another, and one CLOB or LONGCHAR to another, using the Assignment (=) statement or ASSIGN statement. You cannot use the Assignment (=) statement or ASSIGN statement to assign large object data between BLOBs or MEMPTRs and CLOBs or LONGCHARs.
COUNT-OF function

Returns an INTEGER value that is the total number of selected records in the file or files you are using across break groups.

Syntax

```
COUNT-OF ( break-group )
```

**break-group**

The name of a field or expression you named in the block header with the BREAK BY option.

Example

This procedure sorts all customers by state and then calculates the percentage of the total number of customers that are in each state. The COUNT-OF function provides the calculation with the number of customer records in the database.

```
FOR EACH Customer NO-LOCK BREAK BY Customer.State:
   IF LAST-OF(Customer.State) THEN
      DISPLAY 100 * (ACCUM SUB-COUNT BY Customer.State Customer.State) /
               COUNT-OF(Customer.State) FORMAT "99.9999%"
      COLUMN-LABEL "% of Total!Customers".
END.
```

See also

Aggregate phrase

CREATE statement

Creates a record in a table, sets all the fields in the record to their default initial values, and moves a copy of the record to the record buffer.

Data movement

```
Database -> Record buffer -> Screen buffer
```

Syntax

```
CREATE record
   [ USING { ROWID ( nrow ) | RECID ( nrec ) } ] [ NO-ERROR ]
```

**record**

The name of the record or record buffer you are creating.
CREATE statement

To create a record in a table defined for multiple databases, you might have to qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

USING { ROWID ( nrow ) | RECID ( nrec ) }

Supported only for backward compatibility.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.
- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.
- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.
- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.
- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not
be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Example**

The following example creates a record in the order file for each pass through the loop and then updates the record. It also creates an order-line record.

```
r-create.p
REPEAT:
    CREATE Order.
    UPDATE Order.OrderNum Order.CustNum
    VALIDATE(CAN-FIND(Customer OF Order), "Customer does not exist")
    Order.CustNum Order.OrderDate.
REPEAT:
    CREATE OrderLine.
    UPDATE OrderLine.LineNum OrderLine.ItemNum
    VALIDATE(CAN-FIND(Item OF OrderLine), "Item does not exist")
END.
END.
```

This procedure adds Orders and OrderLines to the database. Because the user supplies an order number when updating the order record, that order number is assigned (=) to the OrderNum field of the OrderLine record when the OrderLine record is created.

**Notes**

- When you run procedures that create large numbers of records (for example, during initial data loading), the process runs much faster if you use the No Crash Protection (-i) parameter. See *OpenEdge Deployment: Startup Command and Parameter Reference* for more information on startup parameters. Back up your database before you use this parameter.

- After you create a new record with CREATE, the AVM waits to write the record to the database until after the next statement generates an index entry for the record.

- The CREATE statement causes any related database CREATE triggers to execute. All CREATE triggers execute after the record is actually created. If a CREATE trigger fails (or executes a RETURN statement with the ERROR option), the record creation is undone.

**See also**  
INSERT statement, NEW function (record buffers)

---

**CREATE ALIAS statement**

Creates an alias for a database. Once an alias is created, it can be used in place of the database’s logical name.

**Note:** A database can have more than one alias, but each alias refers to one and only one database.
CREATE ALIAS statement

Syntax

```
CREATE ALIAS alias-string | value ( expression )
   FOR DATABASE logical-name-string | value ( expression )
   [ NO-ERROR ]
```

- **alias-string | value ( expression )**
  
  An unquoted string, quoted string, or CHARACTER expression that represents an alias for the database.

- **FOR DATABASE logical-name-string | value ( expression )**
  
  An unquoted string, quoted string, or CHARACTER expression that represents the logical name of the database.

**Note:** The logical name must already be set.

- **NO-ERROR**
  
  Tells the AVM to allow the alias to be created even if the database is not connected.

  If you CREATE ALIAS for a database that is not connected and omit NO-ERROR, the AVM reports a run-time error.

  **Note:** The NO-ERROR option of the CREATE ALIAS statement behaves differently from the NO-ERROR option of other ABL elements.

**Example**

This procedure creates the alias myalias for database mydb:

```
CREATE ALIAS myalias FOR DATABASE mydb NO-ERROR
```

**Notes**

- The first OpenEdge database connected during a given session receives the DICTDB alias.
- The first database connected that has an _menu file automatically receives the alias FTDB. You can reassign the FTDB alias to any other FAST TRACK database.
- If there is already a database connected with logical name equal to alias, CREATE ALIAS fails.
- If there is an existing alias equal to alias, the existing alias is replaced by the new alias.
- If you want to use an expression for an alias name or logical name, you must use CREATE ALIAS VALUE (expression) FOR DATABASE VALUE (expression).
- When a given database is disconnected, the existing aliases that refer to it are not erased, but remain in the session alias table. Later in the same session, if you connect to a database with the same logical name, the same alias is used again.
- Aliases allow a general purpose application (such as the OpenEdge Data Dictionary) to expect a specific database name. The Dictionary only works on databases with logical
name or alias “DICTDB”. The end user or the application can use CREATE ALIAS to provide the correct alias, in case it is inconvenient to connect the database using the correct logical name. Also, if there are several connected databases, the application can ask the user which one to select, then set the alias accordingly. The Data Dictionary does this when you choose Select Working Database.

- Suppose you connect to a database with logical name MYNAME and compile a procedure that accesses that database. Normally, the saved r-code file contains references to MYNAME.

In a later session, when you want to use the precompiled program, you can connect to your database with the same logical name (MYNAME), or you can connect with a different logical name and set up an alias with the statement CREATE ALIAS “MYNAME” FOR DATABASE logical-name.

- Usually, any alias that exists during the session when you compile a procedure has no effect on the resulting r-code file. When a procedure is compiled, the logical name of the database that is accessed within the procedure is put into the r-code file, not an existing alias. If a procedure accesses more than one database, all of the logical names of accessed databases are placed into the r-code file.

However, any file reference that is qualified with an alias (as opposed to a logical name) generates a new instance of the file for the compilation. This new instance causes the r-code to have the alias reference and not the logical database name reference. Subsequent unqualified references to that same file within the same block, or nested blocks, will resolve to the new alias instance following the usual rules for qualifying. Unqualified references to different files in the same database do not get the alias name, but get the logical name. Anonymous references to a file, previously referenced using the alias qualifier, in a different, non-nested block get the logical name instead of the alias name.

It is simpler to just connect to a database with the desired logical name, leave all references unqualified, not create an alias, and then compile the application. However, sometimes you cannot precompile. In those cases, if you want to compile a procedure so that only the alias gets into the r-code file, then explicitly qualify all file references using the alias. You might want only the alias to get into the r-code file, so you can compile and distribute procedures that will run against any database whose logical name has been assigned the alias contained in the r-code file.

- Changes made to an alias do not take effect within the current procedure. In the following example, alias1.p fails to compile when it reaches the FOR EACH statement, because alias myalias has been created during the compilation:

```sql
/* alias1.p */
/* NOTE: this code does NOT work */
CREATE ALIAS myalias FOR DATABASE sports2000.
FOR EACH myalias.Customer NO-LOCK:
    DISPLAY Customer.Name.
END.
```

To solve this problem, split r-alias1.p into two procedures. For example:
CREATE ALIAS statement

**r-dispmn.p**

```plaintext
FOR EACH myalias.Customer NO-LOCK:
    DISPLAY Customer.Name.
END.
```

**r-alias2.p**

```plaintext
CREATE ALIAS myalias FOR DATABASE sports2000.
RUN r-dispmn.p.
```

CREATE ALIAS affects only subsequent compilations; currently executing procedures are not affected.

- Be careful when using shared buffers with aliases. If you reference a shared buffer after changing the alias that initially was used in defining it, the AVM returns a run-time error. See the following example procedures for details.

Once procedure `r-main.p` is run, it calls `r-makebf.p`, which calls `r-disp6.p`. The alias `myalias` is created in `r-main.p` with reference to database `sports2000`. In `r-makebf.p`, the shared buffer `mybuf` is defined for `myalias.customer`. Then, in the next line, `myalias` is changed, so that it now refers to database `sports2`. When an attempt is made to reference shared buffer `mybuf` in procedure `r-disp6.p`, a run-time error occurs, with the message: "r-disp6.p Unable to find shared buffer for mybuf."

**r-main.p**

```plaintext
CREATE ALIAS myalias FOR DATABASE sports2000.
RUN r-makebf.p.
```

**r-makebf.p**

```plaintext
DEFINE NEW SHARED BUFFER mybuf FOR myalias.Customer.
CREATE ALIAS myalias FOR DATABASE sports2.
RUN r-disp6.p
```

**r-disp6.p**

```plaintext
DEFINE SHARED BUFFER mybuf FOR myalias.Customer.

FOR EACH mybuf NO-LOCK:
    DISPLAY mybuf.
END.
```

- Be careful when accessing a database sequence with an alias that points to a different database than the one used when the alias was defined. If you supply an alias name to the CURRENT-VALUE function or the NEXT-VALUE function, only the database used to define the alias is referenced. In this case, it is preferable to use the
DYNAMIC-CURRENT-VALUE function and DYNAMIC-NEXT-VALUE function instead of the CURRENT-VALUE function and NEXT-VALUE function, respectively.

CREATE automation object statement
(Windows only)

Creates (instantiates) an ActiveX Automation object based on a specified Automation Server connection.

Syntax

```
CREATE expression1 COM-hdl-var
[CONNECT [TO expression2]]
[NO-ERROR]
```

expression1

A character-string expression that evaluates to 1) a unique name of a valid Automation object stored in the system registry or 2) the null string ("").

COM-hdl-var

A COM-HANDLE variable that receives the COM handle to the instantiated Automation object.

[CONNECT [TO expression2]]

Specifies the connection option, together with expression1. The behavior of each connection option depends on the execution status of the Automation Server. Table 19 illustrates this behavior.
<table>
<thead>
<tr>
<th>Connection option</th>
<th>Server execution status</th>
<th>Connection behavior</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Not running</td>
<td>Launches a new instance of the Server, then creates a new instance of the Automation object identified by \textit{expression1}. Often, both the new Server and the new Automation object instance are invisibly created.</td>
</tr>
<tr>
<td>2. CONNECT</td>
<td>Running</td>
<td>Connects to an active (instantiated) Automation object identified by \textit{expression1}. Works for top-level Automation objects only. For example, this works for Excel.Application but fails for Excel.Sheet and Excel.Chart, which are both lower-level Automation objects.</td>
</tr>
<tr>
<td></td>
<td>Not running</td>
<td>Invalid. Always returns an error.</td>
</tr>
<tr>
<td>3. CONNECT TO \textit{expression2}</td>
<td>Running</td>
<td>Creates or connects to an Automation object specified by \textit{expression1} that is associated with the file specified by the pathname in \textit{expression2}. If more than one instance of the Server is running, this option randomly selects one (generally, the first one started). If the specified file is already open within the selected Server, this option connects to the Automation object that is instantiated for that file. If the file is not already open in the selected Server, this option opens the file and instantiates the specified Automation object for it.</td>
</tr>
<tr>
<td></td>
<td>Not running</td>
<td>Creates a new instance of an Automation object specified by \textit{expression1} that is associated with the file specified by the pathname in \textit{expression2}. This option starts a new instance of the Server and instantiates the Automation object for the class that is initialized from the contents of the file. Often, the new Server, as well as the new Automation object, are invisibly created.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>This option fails if \textit{expression2} does not specify a valid file.</td>
</tr>
</tbody>
</table>
Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.
- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do
not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE(message-num) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Example**

The following procedure demonstrates several Automation object instantiations using the four basic connection options. It tries all of the options with the Microsoft® Excel Automation Server. Note that not all Automation Servers support all options. For example in Office 95, there is no Automation object for PowerPoint presentations. Thus, the file connection option (Option 3 in Table 19) does not work.
/* Demonstration of connecting to an Automation Object in Excel using the different connection options. */

DEFINE VARIABLE curDir AS CHARACTER NO-UNDO.
DEFINE VARIABLE cEditor AS CHARACTER NO-UNDO
VIEW-AS EDITOR SIZE 63 BY 1 LABEL "Result:" FONT 2.
DEFINE VARIABLE wordApp1 AS COM-HANDLE NO-UNDO.

DEFINE BUTTON bExit
LABEL "Exit" SIZE 16 BY 1.25 AUTO-GO.
DEFINE BUTTON bStart
LABEL "Option 1 - Start Excel" SIZE 32 BY 1.25.
DEFINE BUTTON bConnect
LABEL "Option 2 - Connect to Active" SIZE 32 BY 1.25.
DEFINE BUTTON bConPerFile
LABEL "Option 3 - Connect per File" SIZE 32 BY 1.25.
DEFINE BUTTON bConnectMon
LABEL "Option 4 - Connect by Extension" SIZE 32 BY 1.25.

ASSIGN
FILE-INFO:FILE-NAME = ".
curDir = FILE-INFO:FULL-PATHNAME.

FORM cEditor SKIP(0.5) bStart SPACE bConnect SPACE bConPerFile SPACE bConnectMon SKIP(0.5) bExit
WITH FRAME a VIEW-AS DIALOG-BOX THREE-D FONT 6.
FRAME a:TITLE = "Testing CREATE Automation Object Statement".
ENABLE ALL WITH FRAME a.

ON CHOOSE OF bStart IN FRAME a DO:
/* Option 1: CREATE expression1 Com-Handle-Var. */
DEFINE VARIABLE excelApp1 AS COM-HANDLE NO-UNDO.

excelApp1:Visible = TRUE.
excelApp1:Range("A1"):Value = "testing CREATE".
ASSIGN cEditor:SCREEN-VALUE = STRING(excelApp1:Range("A1"):Value).
RELEASE OBJECT excelApp1.
END.
You must ensure that any third-party Automation objects you want to instantiate are installed and correctly listed in the registry. For information on what Automation objects you can instantiate, see the documentation for the third-party product. Generally, these are the same Automation objects instantiated by the Visual Basic CreateObject and GetObject functions. You might also be able to view these Automation objects using the OpenEdge COM Object Viewer tool. For more information, see OpenEdge Development: Programming Interfaces.

The instantiation of an Automation object depends on the implementation of the Automation Server itself. Any Server registered for multiple use (REGCLS_MULTIPLE_USE flag) launches a single instance of the Server that handles multiple Automation object instantiation requests. Any Server registered single use (REGCLS_SINGLE_USE flag) launches a new instance of the Server for each instantiated Automation object.

The four connection options in Table 19 compare to the following Visual Basic function calls:

```vbnet
ON CHOOSE OF bConnect IN FRAME a DO:
    /* Option 2: CREATE expression1 Com-Handle-Var CONNECT. */
    DEFINE VARIABLE excelAppl AS COM-HANDLE NO-UNDO.

    CREATE "Excel.Application" excelAppl CONNECT.
    excelAppl:Range("A2").Value = "testing CONNECT".
    MESSAGE "Click me to continue!" VIEW-AS ALERT-BOX.
    ASSIGN cEditor:SCREEN-VALUE = STRING(excelAppl:Range("A2").Value).
    excelAppl:Quit().
    RELEASE OBJECT excelAppl.
END.

ON CHOOSE OF bConPerFile IN FRAME a DO:
    /* Option 3: CREATE expression1 Com-Handle-Var CONNECT TO expression2. */
    DEFINE VARIABLE excelAppl AS COM-HANDLE NO-UNDO.
    DEFINE VARIABLE cFileName AS CHARACTER NO-UNDO
        INITIAL "\WorkSheets\Xplan.xls".

    CREATE "Excel.Sheet" excelAppl CONNECT TO cFileName.
    excelAppl:Visible = TRUE.
    excelAppl:Range("A3").Value = "testing CONNECT TO".
    ASSIGN cEditor:SCREEN-VALUE = STRING(excelAppl:Range("A3").Value).
    RELEASE OBJECT excelAppl.
END.

ON CHOOSE OF bConnectMon IN FRAME a DO:
    /* Option 4: CREATE "" Com-Handle-Var CONNECT TO expression2. */
    DEFINE VARIABLE excelAppl AS COM-HANDLE NO-UNDO.
    DEFINE VARIABLE cFileName AS CHARACTER NO-UNDO
        INITIAL "\WorkSheets\Xplan.xls".

    CREATE "" excelAppl CONNECT TO cFileName.
    excelAppl:Range("A4").Value = "testing CONNECT TO where expression1 = ''".
    MESSAGE "Click me to continue!" VIEW-AS ALERT-BOX.
    ASSIGN cEditor:SCREEN-VALUE = STRING(excelAppl:Range("A4").Value).
    excelAppl:Workbooks:Item(1):SaveAs(curDir + "\zzz.xls").
    excelAppl:Quit().
    RELEASE OBJECT excelAppl.
END.
```
CREATE BROWSE statement

- **Option 1** — CreateObject (class) or GetObject ("", class)
- **Option 2** — GetObject (, class)
- **Option 3** — GetObject (pathname, class)
- **Option 4** — GetObject (pathname)

- Once you create or connect to an Automation object, you can reference its properties and methods.

**See also**  RELEASE OBJECT statement

---

**CREATE BROWSE statement**
*(Windows only; Graphical interfaces only)*

Creates a dynamic read-only browse widget or a dynamic updateable browse widget. Add browse columns to the widget with the ADD-LIKE-COLUMN, ADD-COLUMNS-FROM, and ADD-CALC-COLUMN methods. Specify the query for the widget with the QUERY attribute.

The dynamic updateable browse can only be a NO-ASSIGN browse—you must make all data assignments to the database.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
CREATE BROWSE handle
    [ IN WIDGET-POOL widget-pool-name ]
    [ ASSIGN { attribute=expression } ... ]
    [ trigger-phrase ]
```

- **handle**
  A variable of type HANDLE that the AVM sets for the new widget.

- **IN WIDGET-POOL widget-pool-name**
  Specifies the widget pool in which the object is created. If you do not specify a widget pool, the object is created in the current default widget pool. The browse will go away when its widget pool goes away, or when you delete it with the DELETE OBJECT statement.

- **ASSIGN { attribute=expression } ...**
  Assigns specified values to attributes of the object. The attribute parameter must be the name of a valid attribute for the object and expression must evaluate to a valid value for that attribute.

- **trigger-phrase**
  A trigger phrase associated with the object. For more information, see the Trigger phrase reference entry.
Example

The following example creates a dynamic browse and adds columns to it:

```clp
/* r-dynbrws */
DEFINE VARIABLE name-hdl AS HANDLE NO-UNDO.
DEFINE VARIABLE num-hdl AS HANDLE NO-UNDO.
DEFINE VARIABLE address-hdl AS HANDLE NO-UNDO.
DEFINE VARIABLE calc-col-hdl AS HANDLE NO-UNDO.
DEFINE VARIABLE browse-hdl AS HANDLE NO-UNDO.
DEFINE VARIABLE buff-field-hdl AS HANDLE NO-UNDO.
DEFINE VARIABLE brws-col-hdl AS HANDLE NO-UNDO.
DEFINE VARIABLE jx AS INTEGER NO-UNDO.

DEFINE BUTTON btn-delete LABEL "Delete".
DEFINE BUTTON btn-quit LABEL "&Quit" AUTO-ENDKEY.

DEFINE FRAME MyFrame SKIP(10)
  btn-delete btn-quit
  WITH SIZE 80 BY 22.

DEFINE QUERY q1 FOR Customer SCROLLING.
OPEN QUERY q1 FOR EACH Customer NO-LOCK.
CREATE BROWSE browse-hdl
  ASSIGN
    TITLE = "Dynamic Browse"
    FRAME = FRAME MyFrame:HANDLE
    QUERY = QUERY q1:HANDLE
    X = 2
    Y = 2
    WIDTH = 74
    DOWN = 10
    VISIBLE = YES
    SENSITIVE = TRUE
    READ-ONLY = NO.

ON ROW-DISPLAY OF browse-hdl DO:
  IF VALID-HANDLE(calc-col-hdl) THEN
    calc-col-hdl:SCREEN-VALUE =
  END.
```
CREATE BROWSE statement

**Notes**

- If the browse’s height is set using the DOWN attribute and a browse column is added, the browse’s height may change to ensure that the number of DOWN is preserved. This may be due to the addition of the horizontal scrollbar or the growth of the column header.

- If the browse’s height is set using the HEIGHT-CHARS or HEIGHT-PIXELS attributes, or through direct manipulation, and a browse column is added, the DOWN attribute may change to ensure that the specified height is preserved. This may be due to the addition of the horizontal scrollbar or the growth of the column header.

- The DISPLAY . . . WITH BROWSE browse-name statement cannot be used with a dynamic browse. Instead, the user must set the SCREEN-VALUE attributes.

- A dynamic browse’s validation expression is restricted. It may not contain a CAN-FIND function. To reference the field, the FRAME-VALUE function must be used. The CAN-FIND function will still work for a static browse column.

- If a buffer-field is associated with a dynamic browse column, set the buffer-field’s VALIDATE-EXPRESSION attribute before the dynamic browse column is added to the dynamic browse.

```plaintext
ASSIGN
  num-hdl = browse-hdl:ADD-LIKE-COLUMN("Customer.CustNum").
  name-hdl = browse-hdl:ADD-LIKE-COLUMN("Customer.Name").
  address-hdl = browse-hdl:ADD-LIKE-COLUMN("Customer.Address").
  calc-col-hdl = browse-hdl:ADD-CALC-COLUMN("INT","->,>>,>>9.99","","Credit Left").

/* Refresh needs to be done if ADD-CALC-COLUMN is done after the browse is displayed. In ROW-DISPLAY trigger, we can only set the calc field's screen-value if the handle is set. And the handle is set after the ADD-CALC-COLUMN method is done. */

browse-hdl:refresh().
browse-hdl:EXPANDABLE = YES.

ON ROW-LEAVE OF browse-hdl DO:
  IF browse-hdl:CURRENT-ROW-MODIFIED THEN DO:
    REPEAT jx = 1 TO browse-hdl:NUM-COLUMNS:
      brws-col-hdl = browse-hdl:GET-BROWSE-COLUMN(jx).
      IF brws-col-hdl:MODIFIED THEN DO:
        buff-field-hdl = brws-col-hdl:BUFFER-FIELD.
        "/* If buff-field-hdl is unknown, this is a calculated field and cannot
         be updated */
        IF buff-field-hdl NE ? THEN
          buff-field-hdl:BUFFER-VALUE = brws-col-hdl:SCREEN-VALUE.
        END.
      END.
    END.
  END.
END.

ON CHOOSE OF btn-delete DO:   /* LABEL "DeleteDynBrowse". */
  DELETE WIDGET browse-hdl.
END.

ON CHOOSE OF btn-quit DO:
  QUIT.
END.

ENABLE ALL WITH FRAME MyFrame.
WAIT-FOR CLOSE OF CURRENT-WINDOW.
```
CREATE BUFFER statement

Creates a dynamic buffer object.

Syntax

```
CREATE BUFFER handle FOR TABLE { table-name | table-handle | buffer-handle }
[ BUFFER-NAME buffer-name ]
[ IN WIDGET-POOL widget-pool-name ]
```

**handle**

A variable of type HANDLE that represents the handle of the buffer object.

**FOR TABLE table-name | table-handle | buffer-handle**

A character expression (table-name) that evaluates to a unique database table name or static temp-table name, a temp-table handle (table-handle), or to an existing buffer object handle (buffer-handle), each of which can specify the record source for which to create the buffer object.

If table-name is ambiguous, you must qualify the database table name with a database name or rename the temp-table. Otherwise, if the database table exists in multiple connected databases, the AVM creates the buffer in the first connected database.

**BUFFER-NAME buffer-name**

An expression of type CHARACTER that evaluates, at run time, to the name of the dynamic buffer you are creating. This option lets a dynamic query have multiple buffers for the same table.
IN WIDGET-POOL widget-pool-name

An expression of type CHARACTER that evaluates, at run time, to the name of the widget pool that contains the dynamic buffer.

**Note:** Widget pool names are not case-sensitive.

**Examples**

The following example runs the query “for each customer” dynamically against the Sports2000 database using a purely dynamic buffer with no compile time references at all:

```plaintext
r-crtbuf.p

DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE qh AS HANDLE NO-UNDO.
DEFINE VARIABLE bh AS HANDLE NO-UNDO.
DEFINE VARIABLE fh AS HANDLE NO-UNDO EXTENT 10.

CREATE BUFFER bh FOR TABLE "Customer".
CREATE QUERY qh.

qh:SET-BUFFERS(bh).
qh:QUERY-PREPARE("FOR EACH Customer").
qh:QUERY-OPEN().
qh:GET-FIRST().
DISPLAY bh:NAME.

REPEAT ix = 1 TO 10:
   DISPLAY fh[ix]:NAME STRING(fh[ix]:BUFFER-VALUE).
END.

qh:QUERY-CLOSE().
bh:BUFFER-RELEASE().
DELETE OBJECT bh.
DELETE OBJECT qh.
```

The following code fragment shows several different ways you can create an alternate dynamic buffer for a static temp-table. Note the notation BUFFER tt1:HANDLE and TEMP-TABLE tt1:HANDLE for accessing the default buffer object handle and temp-table object handle, respectively, for the static temp-table, tt1:

```plaintext
DEFINE VARIABLE hbuf AS HANDLE NO-UNDO. /* Default buffer object */
DEFINE VARIABLE htab AS HANDLE NO-UNDO. /* Temp-table object */
DEFINE VARIABLE hbuf1 AS HANDLE NO-UNDO. /* 2nd non-default buffer object */

DEFINE TEMP-TABLE tt1 NO-UNDO
   FIELD x AS CHARACTER.
   hbuf = BUFFER tt1:HANDLE.    /* Static temp-table's default buffer */
   htab = TEMP-TABLE tt1:HANDLE. /* Static temp-table handle (not buffer) */

   /* Different ways to create an alternate temp-table buffer */
CREATE BUFFER hbuf1
   FOR TABLE BUFFER tt1:HANDLE.    /* From static tt's default buffer */
CREATE BUFFER hbuf1 FOR TABLE hbuf. /* From static tt's default buffer */
CREATE BUFFER hbuf1
   FOR TABLE TEMP-TABLE tt1:HANDLE. /* From static tt's handle */
CREATE BUFFER hbuf1 FOR TABLE htab. /* From static tt's handle */
CREATE BUFFER hbuf1 FOR TABLE "tt1". /* From static tt's name */
```
CREATE CALL statement

Notes

- If the character expression, *table-name*, identifies a temp-table defined as REFERENCE-ONLY, the statement sets *handle* to an unbound object that cannot function as a buffer object. To create a valid buffer object for such a table, use FOR TABLE *table-handle* or *buffer-handle* instead.

- Unless you need to use an alternate buffer, the most economical and cleanest way to obtain a buffer object handle for a table is to retrieve the handle for its default buffer. For example:

```plaintext
DEFINE VARIABLE hbuf AS HANDLE NO-UNDO.
DEFINE VARIABLE htab AS HANDLE NO-UNDO.

DEFINE TEMP-TABLE tt2 NO-UNDO
FIELD x AS CHARACTER.

CREATE TEMP-TABLE htab,
htab:TEMP-TABLE-PREPARE( "dynTT" ).

/* Obtaining the default buffer for a table */
hbuf = BUFFER Customer:HANDLE.  /* For a database table */
hbuf = BUFFER tt2:HANDLE.      /* For a static temp-table */
hbuf = htab:DEFAULT-BUFFER-HANDLE. /* For a dynamic temp-table */
```

See also  
CREATE QUERY statement, DEFINE BUFFER statement

CREATE CALL statement

Creates a call object, then stores a handle to it in the handle variable specified. The call object, its attributes, and its methods, are used by applications to invoke logic dynamically.

Syntax

```plaintext
CREATE CALL handle [ IN WIDGET-POOL widget-pool ] [ NO-ERROR ]
```

*handle*

A HANDLE expression that indicates the name of a HANDLE variable into which a handle to the new call object is stored.

*IN WIDGET-POOL widget-pool*

A CHARACTER expression that indicates the name of the widget pool to contain the new call object.

*NO-ERROR*

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:
• Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

• Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

• Use ERROR-STATUS:GET-MESSAGE(message-num) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

• NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

• A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

• When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

• If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Notes**

• Unlike most ABL objects, the call object, by default, is assigned not to the closest unnamed widget pool, but rather to the SESSION widget pool.

• A call object is deleted automatically when its widget pool is deleted. To delete it earlier than its widget pool, use the DELETE OBJECT statement.

**See also**

Call object handle, DELETE OBJECT statement
CREATE CLIENT-PRINCIPAL statement

Creates an instance of a Client-principal object dynamically at run time. Each Client-principal object instance contains information specific to one user login session. This login session may be used as an application or database user identity from an authentication domain registered in the application’s trusted authentication domain registry.

Note: You use a Client-principal object with the SET-CLIENT( ) method or SET-DB-CLIENT function to set the user identity for an ABL session or OpenEdge database. You can have only one active Client-principal object set as the current user at any one point in time for a session or database connection.

Syntax

```
CREATE CLIENT-PRINCIPAL client-principal-handle
```

`client-principal-handle`

A variable of type HANDLE that represents the handle of the Client-principal object.

Note

To use the Client-principal object, you must first register the authentication domain that created the object in the application’s trusted authentication domain registry for the session or database connection. To register an authentication domain, you can do either of the following:

- Use the REGISTER-DOMAIN( ) and LOCK-REGISTRATION( ) methods, which register an authentication domain and then restrict the registration of additional authentication domains, respectively.
- Use the LOAD-DOMAINS( ) method, which loads registered authentication domains from an OpenEdge database and then automatically restricts the registration of additional authentication domains.

See also

Client-principal object handle, LOAD-DOMAINS( ) method, LOCK-REGISTRATION( ) method, REGISTER-DOMAIN( ) method, SET-CLIENT( ) method, SET-DB-CLIENT function

CREATE DATABASE statement

Creates a new OpenEdge database.

Syntax

```
CREATE DATABASE new-database [ FROM old-database [ NEW-INSTANCE ] ]
[ REPLACE ] [ NO-ERROR ]
```

`new-database`

A CHARACTER expression that returns the absolute or relative pathname of the database you want to create. Any relative pathname is relative to the current working directory. If the database already exists, a new database is not created unless you specify REPLACE.
CREATE DATABASE statement

FROM old-database

A CHARACTER expression that returns the name of the database whose schema and data you want to copy to the new database. The value of old-database can be an absolute or relative pathname or one of the special strings "EMPTY", "DEMO", or "SPORTS". If you omit this option, the AVM creates an empty database. Any relative pathname is relative to the current working directory.

NEW-INSTANCE

If specified, the AVM assigns the new database a new globally unique identifier (GUID) value as the database identifier. If not specified, the AVM assigns the new database the same GUID database identifier as the old database.

When you create a new database by copying an existing database provided by OpenEdge (such as the empty database, demo database, or Sports2000 database), the AVM always assigns the new database a new GUID database identifier.

Note: Use this option only when creating a new database by copying an existing database.

REPLACE

If specified and a database already exists with the name specified by new-database, the existing database is deleted and replaced with the new database. If not specified and a database already exists with the name specified by new-database, an error occurs.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.
If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- **NO-ERROR** does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Example**

This procedure prompts for the name of a database to connect. If the database does not exist, the procedure creates it.
CREATE DATASET statement

Creates a ProDataSet object dynamically at run time. The ProDataSet object that is created is empty.

**Note:** You can use the `ADD-BUFFER()` method and `SET-BUFFERS()` method to add buffers to a dynamic ProDataSet object.

**Syntax**

```
CREATE DATASET dataset-handle [ IN WIDGET-POOL widget-pool-name ]
```

`dataset-handle`

A variable of type HANDLE that represents the handle of the dynamic ProDataSet object.

---

**r-credb.p**

```prolog
DEFINE VARIABLE dbname AS CHARACTER NO-UNDO LABEL "Database" FORMAT "x(65)".

/* Prompt the user for the name of a demo database to connect. */
SET dbname HELP "Enter the name of your database."
   WITH FRAME dbname-frame SIDE-LABELS.

/* If the entered name does not have the .db suffix, add it. This is necessary for the search function to work correctly. */
IF LENGTH(dbname) < 3 THEN
   dbname = dbname + ".db".
ELSE IF SUBSTRING(dbname, LENGTH(dbname) - 2) = ".db" THEN
   dbname = dbname + ".db".

/* If the database does not exist, create it from Sports2000. */
IF SEARCH(dbname) = ? THEN DO:
   MESSAGE "Database does not exist. Do you want to create it?"
      VIEW-AS ALERT-BOX QUESTION BUTTONS YES-NO TITLE "Connect Database"
      UPDATE create-it AS LOGICAL.
   IF create-it THEN DO:
      CREATE DATABASE dbname FROM "Sports2000".
      MESSAGE "New database created:" dbname.
      END.
   ELSE UNDO, RETRY.
   END.

/* Connect the database. */
CONNECT VALUE(dbname) -1.
```

**Note**

If you omit the FROM option, the AVM uses the empty database.

**See also**

ALIAS function, CONNECT statement, CONNECTED function, CREATE ALIAS statement, DATASERVERS function, DBCODEPAGE function, DBCOLLATION function, DBRESTRICTIONS function, DBTYPE function, DELETE ALIAS statement, DISCONNECT statement, ERROR-STATUS system handle, FRAME-DB function, LDBNAME function, NUM-DBS function, PDBNAME function, SDBNAME function
CREATE DATA-SOURCE statement

IN WIDGET-POOL widget-pool-name

An expression of type CHARACTER that evaluates, at run time, to the name of the widget pool in which the dynamic ProDataSet object is created.

**Note:** Widget pool names are not case-sensitive.

**Notes**
- If you do not specify a widget pool name, the object is created in the Session unnamed widget pool (not in the closest unnamed widget pool). The object goes away when its widget pool goes away or when you delete it using the DELETE OBJECT statement.
- If the ProDataSet object serves as an OUTPUT parameter and you specify a widget pool, the widget pool must outlive the called procedure.

**Example**
Following is an example of how to create a dynamic ProDataSet object for Orders and their Orderlines:

```pl
DEFINE VARIABLE hDset AS HANDLE NO-UNDO.
DEFINE VARIABLE hRel AS HANDLE NO-UNDO.
CREATE DATASET hDset.
```

**See also**
ProDataSet object handle, DEFINE DATASET statement

CREATE DATA-SOURCE statement

Creates a data-source object dynamically at run time.

**Syntax**

```pl
CREATE DATA-SOURCE data-source-handle [ IN WIDGET-POOL widget-pool-name ]
```

*data-source-handle*

A variable of type HANDLE that represents the handle of the dynamic data-source object.

*IN WIDGET-POOL widget-pool-name*

An expression of type CHARACTER that evaluates, at run time, to the name of the widget pool in which the dynamic data-source object is created.

**Note:** Widget pool names are not case-sensitive.
Note If you do not specify a widget pool name, the dynamic data-source object is created in the closest unnamed widget-pool, by default. The object goes away when its widget pool goes away or when you delete it using the DELETE OBJECT statement.

See also Data-source object handle, DEFINE DATA-SOURCE statement

CREATE QUERY statement

Creates a dynamic query.

Syntax

```
CREATE QUERY handle
  [ IN WIDGET-POOL widget-pool-name ]
```

**handle**

A variable of type HANDLE that represents the handle of the query object.

**IN WIDGET-POOL widget-pool-name**

An expression of type CHARACTER that evaluates, at run time, to the name of the widget pool that contains the dynamic query.

**Note:** Widget pool names are not case-sensitive.

Example

The following example creates a dynamic query with a static buffer and a dynamic predicate (WHERE clause) which is resolved at run time:

**r-crtqry.p**

```
/* r-crtqry.p */

DEFINE VARIABLE hQuery AS HANDLE NO-UNDO.
DEFINE VARIABLE iNumVar AS INTEGER NO-UNDO INITIAL 10.

CREATE QUERY hQuery.

hQuery:SET-BUFFERS(BUFFER Customer:HANDLE).

hQuery:QUERY-PREPARE("FOR EACH Customer WHERE Customer.CustNum < " +
  STRING(iNumVar)).

hQuery:QUERY-OPEN.

REPEAT WITH FRAME y:
  hQuery:GET-NEXT().
  IF hQuery:QUERY-OFF-END THEN LEAVE.
  DISPLAY
    Customer.CustNum
    Customer.Name FORMAT "x(30)"
    Customer.City FORMAT "X(20)".
  END.

hQuery:QUERY-CLOSE()
DELETE OBJECT hQuery.
```
**CREATE SAX-ATTRIBUTES statement**

Creates an instance of a SAX-attributes object and assigns its handle to the handle variable specified. Use this object to access and manage the attribute list for an XML element either being read or written with the SAX-reader or SAX-writer object.

**Syntax**

```
CREATE SAX-ATTRIBUTES handle [ IN WIDGET-POOL pool-name ] [ NO-ERROR ]
```

- `handle`:
  Variable of type HANDLE which stores the handle of the new SAX-attributes object.

- `IN WIDGET-POOL pool-name`:
  Specifies the widget pool where the AVM creates the new object. If you do not specify a widget pool, the AVM creates the object in the current default widget pool.

- `NO-ERROR`:
  Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.
- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.
- Use ERROR-STATUS:GET-MESSAGE(message-num) to retrieve a particular message, where `message-num` is 1 for the first message.
CREATE SAX-ATTRIBUTES statement

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

In ABL, a SAX-attributes object can be automatically created and managed by the SAX parser, or programatically created and managed by you. Automatic SAX-attributes objects are created, populated, and destroyed during the scope of the startElement callback procedure. The startElement callback is called by the SAX-reader object each time the SAX parser encounters new XML element during a read operation. The SAX parser populates the SAX-attributes object, but you may interact with the object during the scope of the startElement callback procedure. For example, you may add elements, update elements, and remove elements from the SAX-attributes object.

At the conclusion of the callback, the SAX-attributes object is deleted and your access to the element list is lost. To save the XML attributes list, you would need to create another SAX-attributes object that is not tied to the scope of the startElement callback procedure. Then, from within the startElement callback, you would use the COPY-SAX-ATTRIBUTES( ) method on the new object and provide a handle to the automatically created SAX-attributes object.

Finally, you would likely pass the XML element and its attributes to a SAX-writer object to concurrently build a new XML document while reading the source XML document.

Example

The following code snippets assembled form one complete example of a concurrent XML read and write operation. The first snippet shows the main block of code:
This snippet contains the callbacks for starting and ending a document read. Note that embedded in the steps of the read operation are the corresponding steps for a concurrent write operation:

```lisp
/* Uses THIS-PROCEDURE as the SAX handler. All callbacks are below. */
lok = hReader:SET-INPUT-SOURCE("file", cFileRead).
lok = hWriter:SET-OUTPUT-DESTINATION("file", cFileWrite).

hReader:SAX-PARSE().
IF ERROR-STATUS:ERROR THEN DO:
    MESSAGE "Problem reading the XML file:" cFileRead.
    MESSAGE ERROR-STATUS:GET-MESSAGE(1).
END.
ELSE
    MESSAGE "XML file converted. Written to" cFileWrite.

DELETE OBJECT hReader.
DELETE OBJECT hWriter.
DELETE OBJECT hSaxAtt.
```

The startElement callback does most of the processing. Depending on the values being read by SAX-reader, the callback decides what to write to the new XML document:
The last snippet completes the set of callback procedures needed for this example:

See also  SAX-attributes object handle
CREATE SAX-READER statement

Syntax

```
CREATE SAX-READER handle
   [ IN WIDGET-POOL pool-name ] [ NO-ERROR ]
```

handle

A variable of type HANDLE into which CREATE SAX-READER stores the new handle.

IN WIDGET-POOL pool-name

A CHARACTER expression indicating the widget pool in which the object is created. If you do not specify a widget pool, the object is created in the current default widget pool.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE(message-num) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the
error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

See also SAX-reader object handle

CREATE SAX-WRITER statement

Creates an instance of a SAX-writer object and assigns its handle to the handle variable specified. Use this object to write an XML document using the SAX interface.

Syntax

```
CREATE SAX-WRITER handle [ IN WIDGET-POOL pool-name ] [ NO-ERROR ]
```

**handle**

Variable of type HANDLE which stores the handle of the new SAX-writer object.

**IN WIDGET-POOL pool-name**

Specifies the widget pool where the AVM creates the new object. If you do not specify a widget pool, the AVM creates the object in the current default widget pool.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the
CREATE SERVER statement

ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.
- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.
- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.
- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

See also SAX-writer object handle

CREATE SERVER statement

Creates an instance of a server object and assigns its handle to the handle variable you specify.

Syntax

```
CREATE SERVER handle
  [ ASSIGN { attribute = expression } ... ]
```

handle

A variable of type HANDLE into which CREATE SERVER stores the new server handle.
ASSIGN \{ attribute = expression \} ... 

Assigns specified values to attributes of the handle. The attribute parameter must be the name of a valid attribute for a server handle, and the expression parameter must evaluate to a valid value for the attribute.

**Note**

You can use a server handle as a connection point to an AppServer™. For more information on server handles, see the Server object handle entry. For more information on AppServers, see OpenEdge Application Server: Developing AppServer Applications.

**See also**

DELETE OBJECT statement, RUN statement, Server object handle

---

**CREATE SERVER-SOCKET statement**

Creates an instance of a server socket object and assigns it to the handle variable specified. It is through this object that a socket-based server application can listen for connections on a TCP/IP port.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
CREATE SERVER-SOCKET handle [ NO-ERROR ]
```

*handle*

Variable of type HANDLE into which the CREATE SERVER-SOCKET statement stores the new server socket handle.

*NO-ERROR*

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object.
CREATE SOAP-HEADER statement

Creates an instance of a SOAP-header object dynamically at run time, and assigns its handle to the specified handle variable.

Syntax

```
CREATE SOAP-HEADER handle [ IN WIDGET-POOL widget-pool-name ]
```

*handle*

A variable of type HANDLE that represents the handle of the SOAP-header object.
CREATE SOAP-HEADER-ENTRYREF statement

IN WIDGET-POOL  \textit{widget-pool-name}

An expression of type CHARACTER that evaluates to the name of the widget pool in which the dynamic SOAP-header object is created.

\textbf{Note:} Widget pool names are not case-sensitive.

\textbf{Notes}

- Use the SOAP-header object to pass an input parameter to a response callback procedure and an output parameter to a request callback procedure. The SOAP HEADER object passed to the response callback is implicitly created by the AVM. In order to pass a SOAP HEADER object back from the request callback, the application needs to explicitly create it or use an object that it has previously saved.

- The SOAP-header object is either implicitly created by the AVM or explicitly created by the application using the CREATE SOAP-HEADER statement. In either case, the application is responsible for deleting the object.

You can delete a SOAP-header object and its underlying XML in one of two ways. You can:

- Use the DELETE OBJECT statement to delete the SOAP-header object directly.

- Set the \texttt{lDeleteOnDone} parameter in the request header callback procedure to TRUE, which directs the AVM to delete the SOAP header object after it copies the object’s contents to the outbound SOAP message.

For more information about deleting SOAP-header objects, see \textit{OpenEdge Development: Web Services}.

\textbf{See also} \textit{SOAP-header object handle}

\section*{CREATE SOAP-HEADER-ENTRYREF statement}

Creates an instance of a SOAP-header-entryref object dynamically at run time, and assigns its handle to the specified handle variable.

\textbf{Syntax}

\begin{verbatim}
CREATE SOAP-HEADER-ENTRYREF  \textit{hshEntry}  [ IN WIDGET-POOL \textit{widget-pool-name} ]
\end{verbatim}

\begin{itemize}
  \item \textit{hshEntry}

    A variable of type HANDLE that represents the handle of the SOAP-header-entryref object.

  \item \textbf{IN WIDGET-POOL}  \textit{widget-pool-name}

    An expression of type CHARACTER that evaluates to the name of the widget pool in which the dynamic SOAP-header-entryref object is created. A SOAP-header-entryref object is created in the closest unnamed widget-pool, by default.
\end{itemize}
**CREATE SOCKET statement**

Creates a socket object and assigns it to the handle variable specified. It is through this object that the application can connect to a TCP/IP port and read and write on the socket bound to the port.

**Syntax**

```
CREATE SOCKET handle [ NO-ERROR ]
```

**handle**

Variable of type HANDLE into which CREATE SOCKET stores the new socket handle.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the **ERROR-STATUS system handle**. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the **ERROR-STATUS:ERROR** attribute to see if the AVM raised the ERROR condition.

- Check if the **ERROR-STATUS:NUM-MESSAGES** attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block **without** a CATCH end block treat errors as warnings and do not raise ERROR, do not set the **ERROR-STATUS:ERROR** attribute, but do add messages to the **ERROR-STATUS system handle**. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block **with** a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the **ERROR-STATUS system handle**.

- Use **ERROR-STATUS:GET-MESSAGE( message-num )** to retrieve a particular message, where **message-num** is 1 for the first message.

---

**Note:** Widget pool names are not case-sensitive.

**Note**

The SOAP-header-entryref object is explicitly created by the application using the CREATE SOAP-HEADER-ENTRYREF statement. The application is responsible for deleting this object. Use the DELETE OBJECT statement to delete a SOAP-header-entryref object without deleting its underlying XML. Use the DELETE-HEADER-ENTRY() method to delete the XML underlying the SOAP-header-entryref object without deleting the object.

**See also** SOAP-header-entryref object handle
If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- **NO-ERROR** does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

CREATE SERVER-SOCKET statement, DELETE OBJECT statement, Server socket object handle, Socket object handle

---

### CREATE TEMP-TABLE statement

Creates a TEMP-TABLE dynamically at run time. The TEMP-TABLE that is created is empty and must be defined using ADD/CREATE methods.

**Syntax**

```
CREATE TEMP-TABLE handle
    [ IN WIDGET-POOL widget-pool-name ]
```

**handle**

A variable of type HANDLE that represents the handle of the TEMP-TABLE object.

**IN WIDGET-POOL widget-pool-name**

An expression of type CHARACTER that evaluates, at run time, to the name of the widget pool that contains the dynamic TEMP-TABLE.

**Note:** Widget pool names are not case-sensitive.
Example

The following example creates a TEMP-TABLE like the Order table and populates it from the Order table. In addition, the corresponding SalesRep name is added from the SalesRep table, as shown:

r-cretmpt.p

```
DEFINE VARIABLE tth AS HANDLE NO-UNDO.
DEFINE VARIABLE bh AS HANDLE NO-UNDO.
DEFINE VARIABLE qh AS HANDLE NO-UNDO.
DEFINE VARIABLE buf-ord-hndl AS HANDLE NO-UNDO.
DEFINE VARIABLE buf-rep-hndl AS HANDLE NO-UNDO.
DEFINE VARIABLE fld1 AS HANDLE NO-UNDO.
DEFINE VARIABLE fld2 AS HANDLE NO-UNDO.

/* Get database table handles */
buf-ord-hndl = BUFFER Order:HANDLE.
buf-rep-hndl = BUFFER SalesRep:HANDLE.

/* Create an empty, undefined TEMP-TABLE */
CREATE TEMP-TABLE tth.

/* Give it Order table's fields & indexes */
tth:CREATE-LIKE(buf-ord-hndl).

/* Add field like SalesRep.RepName */
tth:ADD-LIKE-FIELD("RepName","SalesRep.RepName").

/* No more fields will be added */
tth:TEMP-TABLE-PREPARE("ordx").

/* Get the buffer handle for the temp-table */
bh = tth:DEFAULT-BUFFER-HANDLE.

/* Populate the temp-table from order */
FOR EACH Order NO-LOCK:
  bh:BUFFER-CREATE.
  bh:BUFFER-COPY(buf-ord-hndl).
  /* Add the corresponding salesrep name */
  FIND SalesRep NO-LOCK WHERE SalesRep.SalesRep = Order.SalesRep NO-ERROR.
  IF AVAILABLE SalesRep THEN
    bh:BUFFER-COPY(buf-rep-hndl,?,"RepName,repname").
  END.

/* Run a query to access the TEMP-TABLE */
CREATE QUERY qh.
qh:SET-BUFFERS(bh).
qh:QUERY-PREPARE("FOR EACH ordx WHERE ordx.OrderNum < 50 BY ordx.RepName").
qh:QUERY-OPEN().

fld1 = bh:BUFFER-FIELD("OrderNum").
fld2 = bh:BUFFER-FIELD("RepName").

/* Display the order number and the salesrep name */
REPEAT:
  qh:GET-NEXT().
  IF qh:QUERY-OFF-END THEN LEAVE.
  DISPLAY fld1:BUFFER-VALUE() FORMAT "X(10)".
  DISPLAY fld2:BUFFER-VALUE() FORMAT "X(20)".
END.

qh:QUERY-CLOSE().
bh:BUFFER-RELEASE().
delete object tth.
```

Notes

- Once the TEMP-TABLE fields and indexes are defined using the ADD/CREATE methods, the definition must be terminated by using the TEMP-TABLE-PREPARE method before the TEMP-TABLE can be used.
• Once the TEMP-TABLE is prepared, it can be manipulated by using its buffer object handle which is retrieved using the DEFAULT-BUFFER-HANDLE attribute. All the BUFFER methods are available to the dynamic TEMP-TABLE.

• The dynamic temp-table object is scoped like the buffer object. It is created in a widget pool and ends when the widget pool ends or when it is deleted with the DELETE OBJECT statement. You may not delete the default buffer object belonging to a dynamic temp-table.

• Errors for dynamic temp-tables do not automatically raise the ERROR condition since they occur inside a widget expression. All the methods that can have errors return FALSE if an error occurs, so they must be tested. If NO-ERROR is in effect in the statement containing the widget reference, no messages display, but they can be retrieved from the ERROR-STATUS system handle.

See also DEFINE TEMP-TABLE statement, TEMP-TABLE-PREPARE( ) method

CREATE widget statement

Creates a dynamic object, such as a widget object.

Note: Does not apply to SpeedScript programming.

Syntax

```
CREATE { BUTTON | COMBO-BOX
       | CONTROL-FRAME | DIALOG-BOX
       | EDITOR | FILL-IN
       | FRAME | IMAGE
       | MENU | MENU-ITEM
       | RADIO-SET | RECTANGLE
       | SELECTION-LIST | SLIDER
       | SUB-MENU | TEXT
       | TOGGLE-BOX | WINDOW
       | VALUE ( string-expression )
    } handle [ IN WIDGET-POOL pool-name ]
    [ ASSIGN { attribute = expression } ... ]
    [ trigger-phrase ]
```

VALUE ( string-expression )

An expression of type CHARACTER that evaluates to the type of object you want to create (for example, BUTTON) with any combination of uppercase and lowercase characters.

handle

A variable of type HANDLE that the AVM sets for the new widget.
CREATE widget statement

IN WIDGET-POOL pool-name

Specifies the widget pool in which the object is created. If you do not specify a widget pool, the object is created in the current default widget pool.

ASSIGN \{ attribute = expression \} ...

Assigns specified values to attributes of the object. The attribute parameter must be the name of a valid attribute for the object and expression must evaluate to a valid value for that attribute.

trigger-phrase

A trigger phrase associated with the object. For more information, see the Trigger phrase reference entry.

Example

This procedure creates a dynamic button that displays a list of customer names:

```
r-dynbut.p

DEFINE VARIABLE but1 AS HANDLE NO-UNDO.
DISPLAY "Dynamic Button Example" SKIP(3) WITH FRAME x SIDE-LABELS.
OPEN QUERY all-custs FOR EACH Customer.
GET FIRST all-custs.
DISPLAY Customer.Name WITH FRAME x.
CREATE BUTTON but1 ASSIGN
  \{ ROW = 3 \}
  \{ COLUMN = 5 \}
  \{ LABEL = "Next Customer" \}
  \{ FRAME = FRAME x:HANDLE \}
  \{ SENSITIVE = TRUE \}
  \{ VISIBLE = TRUE \}
TRIGGERS:
  ON CHOOSE DO:
    \{ GET NEXT all-custs. \}
    \{ DISPLAY Customer.Name WITH FRAME x. \}
  END.
END TRIGGERS.
WAIT-FOR WINDOW-CLOSE OF CURRENT-WINDOW.
```

Notes

- Attribute assignments you specify in the CREATE widget statement are processed in the order they appear. In some cases you must supply the attributes in proper order. For example, you cannot set the SENSITIVE or VISIBLE attributes for a field-level widget until you have set its FRAME attribute.

- If you are setting the FORMAT attribute and specifying an initial SCREEN-VALUE for the widget, assign the FORMAT before the SCREEN-VALUE. Otherwise, the default format is applied to the SCREEN-VALUE which might cause truncation or other formatting errors.

- You can use the ASSIGN option to assign a widget ID value to the WIDGET-ID attribute for this object. If you have enabled application-defined widget IDs in your ABL GUI application, by specifying the Use Widget ID (-usewidgetid) startup parameter, then the AVM uses this widget ID when it creates the widget at run time, instead of using the
CREATE WIDGET-POOL statement

Creates a named or unnamed widget pool in which to contain most dynamic widgets and other handle-based objects created during an ABL session.

Note: Does not apply to SpeedScript programming.

Syntax

```
CREATE WIDGET-POOL
  [ pool-name [ PERSISTENT ] ]
  [ NO-ERROR ]
```

**pool-name**

A character-string expression that specifies the name for a named widget pool you are creating. Widget pool names are not case sensitive.

If you omit this option, an unnamed widget pool is created and scoped to the procedure or class-based method. That is, a routine-scoped unnamed widget pool and its contents remain in effect as long as the procedure or method is on the call stack, and the pool and its contents are automatically deleted when the procedure or method is removed from the call stack.

**PERSISTENT**

Specifies that the named widget pool is persistent. This means that the pool and any widgets in it remain allocated after the current procedure or method terminates. If you do not specify this option, the pool and its contents are automatically deleted when procedure or method execution ends.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not
done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.
CREATE WIDGET-POOL statement

Example

The following example lets you create a series of dynamic buttons. All the buttons are created within a named widget pool. Because the widget pool is created within a trigger, it is defined as persistent so that it remains allocated after the trigger ends. You can at any time choose to delete the entire widget pool and start over.

r-widpl.p

```
DEFINE VARIABLE wh AS HANDLE NO-UNDO.

DEFINE BUTTON b_create LABEL "Create Button".
DEFINE BUTTON b_del LABEL "Delete Buttons".
DEFINE BUTTON b_quit LABEL "Quit"

TRIGGERS:
   ON CHOOSE DO:
      IF VALID-HANDLE(wh) THEN
         DELETE WIDGET-POOL "new-buttons".
         QUIT.
      END.

DEFINE FRAME butt-frame
   b_create b_del b_quit
WITH ROW SCREEN-LINES - 2.

DEFINE FRAME new-buttons
WITH SIZE 76 BY 11 CENTERED ROW 2 TITLE "New Buttons".

ON CHOOSE OF b_create IN FRAME butt-frame DO:
   STATUS INPUT "Press RETURN to select a new button".
   IF wh = ? OR NOT VALID-HANDLE(wh) THEN
      CREATE WIDGET-POOL "new-buttons" PERSISTENT.
   END.

   CREATE BUTTON wh IN WIDGET-POOL "new-buttons" ASSIGN
      FRAME = FRAME new-buttons:HANDLE
      ROW = RANDOM(2, 9)
      COLUMN = RANDOM(2, 58)
      LABEL = "BUTTON " + STRING(ETIME)
      SENSITIVE = TRUE
      VISIBLE = TRUE
      TRIGGERS:
         ON CHOOSE PERSISTENT RUN dispmsg.
   END.

ON CHOOSE OF b_del IN FRAME butt-frame DO:
   IF VALID-HANDLE(wh) THEN
      DELETE WIDGET-POOL "new-buttons".
      STATUS INPUT.
   END.

ENABLE b_create b_del b_quit WITH FRAME butt-frame.

DO ON ENDKEY UNDO, LEAVE:
   WAIT-FOR CHOOSE OF b_quit IN FRAME butt-frame.
END.

IF VALID-HANDLE(wh) THEN
   DELETE WIDGET-POOL "new-buttons".

PROCEDURE dispmsg:
   MESSAGE "You chose button " SELF:LABEL.
END PROCEDURE.
```

Notes

- The AVM automatically creates a persistent unnamed widget pool (session widget pool) at the start of each session. Most applications use only this session widget pool.
• In general, unnamed widget pools cannot persist beyond the scope of the procedure or method in which they are created, except the session widget pool, which is created by the AVM.

• If you create an unnamed widget pool in the main block of a persistent procedure or you instantiate a class where the USE-WIDGET-POOL option is defined somewhere in its hierarchy, the AVM creates an object-persistent unnamed widget pool that persists for the lifetime of the persistent procedure or class-based object, respectively. This object-persistent widget pool then becomes the default widget pool for any internal procedure of the persistent procedure or any method of the instantiated class that is invoked from outside the respective persistent procedure or instantiated class. However, any routine-scoped unnamed widget pool created by these internal procedures or methods supersedes this object-persistent widget pool. For more information on the USE-WIDGET-POOL option, see the CLASS statement reference entry.

• When you create an unnamed widget pool, it automatically becomes the default widget pool. Each subsequent dynamically created widget is placed in this unnamed pool unless you specifically assign it to another pool. This unnamed pool remains the default widget pool until it is deleted or you create another unnamed widget pool. Thus, if you create no unnamed widget pools, all dynamically created widgets go into the session widget pool, unless assigned to another pool. If you create any additional unnamed widget pools, either object-persistent or routine-scoped, the most locally scoped and recently created unnamed widget pool becomes the default widget pool for all subsequently created dynamic widgets.

• Persistent widget pools remain allocated until they are explicitly deleted (with the DELETE WIDGET-POOL statement) or until the end of the ABL session that created them.

• All named widget pools are globally scoped. While a named widget pool is allocated, any procedure within the same process can access that widget pool. The name of a widget pool must be unique among all widget pools for the process. If you try to create a widget pool with the same name as an existing pool, the AVM raises the ERROR condition.

• If a recursive procedure or method creates an unnamed widget pool, each iteration of that procedure or method creates a separate pool. If a recursive routine creates a named widget pool, you must ensure that only one iteration creates the pool (where all iterations can share it) or use a different name in each iteration (where each creates and uses its own pool).

• You might want to create a new, unnamed widget pool just before invoking a new procedure or method and then delete that pool when the procedure or method returns. This ensures that any dynamic widgets created by that procedure or method in the default pool are deleted immediately. For example:

```
CREATE WIDGET-POOL.
RUN xyz.p.
DELETE WIDGET-POOL.
```

Similarly, you might want to store all dynamic widgets for a subsystem within a specific named pool. For example:
In this example, the procedure ord-ent.p must reference the oe-pool for each dynamic widget it creates.

**See also** CLASS statement, CREATE widget statement, DELETE WIDGET-POOL statement

### CREATE X-DOCUMENT statement

Creates a handle for an XML document object. To use the XML document, you must add new nodes using the CREATE-NODE( ) method, the CREATE-NODE-NAMESPACE( ) method, or populate the document from an existing file using the LOAD( ) method.

**Note:** To ensure consistency across all nodes in an XML document, use either the CREATE-NODE-NAMESPACE( ) method or the CREATE-NODE( ) method to build an XML document; do not use both methods within a single document.

**Syntax**

```
CREATE X-DOCUMENT handle [ IN WIDGET-POOL widget-pool-name ]
```

*handle*

A variable of type HANDLE into which CREATE X-DOCUMENT stores the new handle.

*IN WIDGET-POOL widget-pool-name*

An expression of type CHARACTER that evaluates, at run time, to the name of the widget pool that contains the XML document object.

**Note:** Widget pool names are not case-sensitive.

**Example**

The following code fragment depicts creating an XML document object:

```
DEFINE VARIABLE hXdoc AS HANDLE NO-UNDO.
.
CREATE X-DOCUMENT hXdoc.
.
```

**See also** CREATE X-NODEREF statement, DELETE OBJECT statement, X-document object handle, X-noderef object handle
CREATE X-NODEREF statement

Creates a handle which can be used as a parameter or return-value for methods which will associate the handle with an XML node. This object is not a node in its own right, but merely a way to provide access to the underlying XML node.

Syntax

```
CREATE X-NODEREF handle [ IN WIDGET-POOL widget-pool-name ]
```

**handle**

A valid X-noderef object handle to use for the new XML node.

**IN WIDGET-POOL widget-pool-name**

An expression of type CHARACTER that evaluates, at run time, to the name of the widget pool that contains the XML node.

**Note:** Widget pool names are not case-sensitive.

An X-noderef object is not in a fully usable state until it has been associated with an X-document. Before this, you can only access its HANDLE, TYPE, PRIVATE-DATE, and UNIQUE-ID attributes without error. To avoid run-time errors, the code below shows one way to test the status of an X-noderef object:

```
cType = X-noderef:SUBTYPE NO-ERROR.
IF VALID-HANDLE(X-noderef) AND cType = 'ELEMENT' THEN DO:
    /*** your code ***/
END.
```

Example

The following code fragment depicts creating an XML document node reference and using it to create a node:

```
DEFINE VARIABLE hXdoc AS HANDLE NO-UNDO.
    . . .
CREATE X-DOCUMENT hXdoc.
CREATE X-NODEREF hXnode.
hXdoc:CREATE-NODE(hXnode,"City","ELEMENT").
    . . .
```

See also

CREATE X-DOCUMENT statement, DELETE OBJECT statement, X-document object handle, X-noderef object handle
CURRENT-CHANGED function

Returns TRUE if the copy of the record in the buffer after executing a FIND CURRENT or GET CURRENT differs from the copy of the record in the buffer before executing the FIND CURRENT or GET CURRENT. That is, if the current application changes the record, but no other user changes the record during its scope in the current application, CURRENT-CHANGED returns FALSE.

Syntax

```
CURRENT-CHANGED record
```

*record*

The name of a table or buffer.

Example

The following example finds the first customer record with NO-LOCK and makes it available to the user to review and change:

```
r-currch.p
```

```plaintext

ON GO OF FRAME upd DO:
  DO TRANSACTION:
    FIND CURRENT Customer EXCLUSIVE-LOCK.
    IF CURRENT-CHANGED Customer THEN DO:
      MESSAGE "This record has been changed by another user" SKIP
      "Please re-enter your changes." VIEW-AS ALERT-BOX.
      RETURN NO-APPLY.
    END.
  END.
  FIND CURRENT Customer NO-LOCK.
END.

FIND FIRST Customer NO-LOCK.
DO ON ENDKEY UNDO, LEAVE:
  WAIT-FOR "GO" OF FRAME upd.
END.
```

While the user reviews the record, other users can change it. After the user makes a change of their own and enters GO in the frame, the first FIND CURRENT statement refetches the current customer record with an EXCLUSIVE-LOCK (preventing other users from reading or updating it). Then, the CURRENT-CHANGED function compares the contents of the customer record with the copy of the customer record that was in the buffer before the FIND CURRENT statement. If it differs, the CURRENT-CHANGED function returns a TRUE value, prints a message, and displays the contents of the customer record contained in the buffer. The RETURN NO-APPLY option prevents the program from ending and gives the user another chance to change the customer record.
The CURRENT-CHANGED function returns a FALSE value if the copy of the customer record that is in the buffer was not modified. After verifying that the copy of the record has not changed, the ASSIGN statement updates the customer record and a second FIND CURRENT statement downgrades the record to NO-LOCK. Thus, while the user has ample time to review and change the record, the actual transaction time is kept to a minimum to allow other users access.

Notes

- The CURRENT-CHANGED function is valid only when called after a FIND CURRENT or GET CURRENT statement.

- If a client application modifies the buffer, the AVM compares the newly read record with the buffer contents from that application, rather than with the record read from the server. The CURRENT-CHANGED function continues to return a value based on the contents of the buffer until the next FIND CURRENT or GET CURRENT operates on that buffer or until the buffer goes out of scope or is released.

- The CURRENT-CHANGED function cannot check the current values against the initial values of BLOB or CLOB fields. If you use CURRENT-CHANGED on a ProBindingSource’s data source that contains a BLOB or a CLOB field, it raises an error unless you set the ProBindingSource’s NoLOBs property to TRUE.

See also FIND statement, GET statement, LOCKED function

CURRENT-LANGUAGE function

Returns the current value of the CURRENT-LANGUAGE variable.

Note: Does not apply to SpeedScript programming.

Syntax

```
CURRENT-LANGUAGE
```

Example

The following example displays a message indicating the setting of your CURRENT-LANGUAGE:

```
r-curlng.p

DEFINE VARIABLE cur-lang AS CHARACTER NO-UNDO.

cur-lang = CURRENT-LANGUAGE.

IF cur-lang = "?" THEN
   MESSAGE "Your current language is not set."
ELSE
   MESSAGE "Your current language is" cur-lang.
```

Notes

- An r-code file may contain several text segments each associated with a different language. The setting of the CURRENT-LANGUAGE variable determines from which r-code text segment the AVM reads character-string constants.
• If the value of CURRENT-LANGUAGE is a quoted question mark ("?") , the AVM reads character-strings from the default text segment.

• The value of CURRENT-LANGUAGE might be a comma-separated list of language names. If so, the AVM searches r-code for a text segment that matches the first language in the list. If that segment is not found, then it searches for a text segment for the next entry in the list until a segment is found.

• You can initialize the CURRENT-LANGUAGE variable with the Language (-lng) parameter.

• The behavior of CURRENT-LANGUAGE when one procedure calls another is as follows:
  – If a procedure changes the value of CURRENT-LANGUAGE, calls from the procedure to the CURRENT-LANGUAGE function return the name of the new language, but the procedure continues to use the character strings of the original language.
  – If the procedure then runs another procedure, when the called procedure gets control, calls from the called procedure to the CURRENT-LANGUAGE function return the name of the new language, and the called procedure uses the character strings of the new language.
  – When the called procedure finishes and control returns to the original procedure, calls from the original procedure to the CURRENT-LANGUAGE function return the name of the new language, but the original procedure continues to use the character strings of the original language.

See also  COMPILE statement, CURRENT-LANGUAGE statement

CURRENT-LANGUAGE statement

Sets the CURRENT-LANGUAGE variable for the current ABL session.

Note:  Does not apply to SpeedScript programming.

Syntax

\[
\text{CURRENT-LANGUAGE} = \text{string-expression}
\]

\text{string-expression}

A character-string expression that specifies a language name or a comma-separated list of language names.

Example

This example procedure uses the CURRENT-LANGUAGE function to find the current language, prompts the user to choose a new language, and then uses the CURRENT-LANGUAGE statement to reset and display the name of the new current language:
CURRENT-RESULT-ROW function

Returns the number of the current row of a specified query as an INTEGER value.

Notes

- The value of CURRENT-LANGUAGE might be a comma-separated list of language names. If so, the AVM searches r-code for a text segment that matches the first language in the list. If that segment is not found, then it searches for a text segment for the next entry in the list until a segment is found.

- You can initialize the CURRENT-LANGUAGE variable with the Language (-lng) parameter.

- The behavior of CURRENT-LANGUAGE when one procedure calls another is as follows:

  - If a procedure changes the value of CURRENT-LANGUAGE, calls from the procedure to the CURRENT-LANGUAGE function return the name of the new language, but the procedure continues to use the character strings of the original language.

  - If the procedure then runs another procedure, when the called procedure gets control, calls from the called procedure to the CURRENT-LANGUAGE function return the name of the new language, and the called procedure uses the character strings of the new language.

  - When the called procedure finishes and control returns to the original procedure, calls from the original procedure to the CURRENT-LANGUAGE function return the name of the new language, but the original procedure continues to use the character strings of the original language.

COMPILE statement, CURRENT-LANGUAGE statement

r-chglng.p

```r
DEFINE VARIABLE cur-lang AS CHARACTER FORMAT "x(10)" VIEW-AS RADIO-SET
  RADIO-BUTTONS czech,  "Czech",
         danish,  "Danish",
         dutch,   "Dutch",
         english, "English",
         french,  "French",
         german,  "German",
         hungar,  "Hungarian",
         italian,  "Italian",
         norweg,  "Norwegian",
         polish,  "Polish",
         portug,  "Portuguese",
         swedish, "Swedish".

cur-lang = IF CURRENT-LANGUAGE = "?" THEN "English" ELSE CURRENT-LANGUAGE.

UPDATE cur-lang NO-LABELS.

CURRENT-LANGUAGE = cur-lang.
MESSAGE "New language is" CURRENT-LANGUAGE.
```
CURRENT-RESULT-ROW function

Syntax

CURRENT-RESULT-ROW ( query-name )

query-name

A character expression that evaluates to the name of a currently open, scrolling query. If
query-name does not resolve to the name of a query, or if the query is not open or not
scrolling, then the function returns the Unknown value (?).

Note: Searching for a query using a handle is more efficient than a character expression.
The AVM resolves a character expression at run time by searching in the current
routine for a static query with that name. If not found, the AVM searches the
enclosing main procedure. If still not found, the AVM searches up through the
calling programs of the current routine, and their main procedures. Since a handle
uniquely identifies a query, no such search is required. Use the query object handle’s CURRENT-RESULT-ROW attribute to avoid a run-time search.

Example

The following example uses the QUERY-OFF-END function to determine when to leave the
REPEAT loop:

r-resrow.p

DEFINE QUERY cust-query FOR Customer SCROLLING.
OPEN QUERY cust-query FOR EACH Customer WHERE Customer.Country = "USA".
REPEAT:
   GET NEXT cust-query.
   IF QUERY-OFF-END("cust-query") THEN LEAVE.
   DISPLAY CURRENT-RESULT-ROW("cust-query") LABEL "Result Row"
END.

Notes

• To use the CURRENT-RESULT-ROW function with a query, the query must be
associated with a browse widget or you must define the query with the SCROLLING
option. For more information on query definitions, see the reference entry for the DEFINE
QUERY statement.

• If the query is empty, CURRENT-RESULT-ROW returns the Unknown value (?).

• If the query is positioned before the first record, CURRENT-RESULT-ROW returns the
value 1. If the query is positioned beyond the last record, CURRENT-RESULT-ROW
returns a value 1 greater than the number of rows in the query result list.

• When possible, the AVM performs optimizations for GET LAST and REPOSITION
statements. These optimizations make the results list invalid. At that point,
CURRENT-RESULT-ROW returns the Unknown value (?). These optimizations do not
occur if the query is opened with the PRESELECT option or has an associated browse
widget.

CLOSE QUERY statement, CURRENT-RESULT-ROW attribute, DEFINE BROWSE
statement, DEFINE QUERY statement, GET statement, NUM-RESULTS function, OPEN
QUERY statement, REPOSITION statement
CURRENT-VALUE function

Returns the current INT64 value of a sequence defined in the Data Dictionary.

Syntax

```
CURRENT-VALUE ( sequence [ , logical-dbname ] )
```

**sequence**

An identifier that specifies the name of a sequence defined in the Data Dictionary.

**logical-dbname**

An identifier that specifies the logical name of the database in which the sequence is defined. The database must be connected. You can omit this parameter if the sequence name is unambiguous. If a sequence with this name exists in more than one connected database, then you must specify `logical-dbname`.

Example

The following example finds the current value of the NextCustNum sequence and then looks for Orders with that Customer number:

```
r-curval.p
```

```pascal
DEFINE VARIABLE cur-cust NO-UNDO LIKE Customer.CustNum.

cur-cust = CURRENT-VALUE(NextCustNum).
IF CAN-FIND(FIRST Order WHERE Order.CustNum = cur-cust) THEN
FOR EACH Order NO-LOCK WHERE Order.CustNum = cur-cust,
   EACH OrderLine OF Order NO-LOCK
      BREAK BY Order.OrderNum:
         IF FIRST-OF(Order.OrderNum) THEN
            DISPLAY Order.OrderNum Order.OrderDate Order.CustNum
            WITH FRAME order-info CENTERED ROW 2 1 COL.
            DISPLAY OrderLine.
         END.
ELSE DO:
   FIND FIRST Customer WHERE Customer.CustNum = cur-cust NO-LOCK NO-ERROR.
   IF AVAILABLE Customer THEN
      MESSAGE "No Orders Exist for Customer " + Customer.Name + ", " + STRING(Customer.CustNum)
      VIEW-AS ALERT-BOX INFORMATION BUTTONS OK TITLE "No Orders".
   ELSE
      MESSAGE "Customer number" cur-cust "does not exist."
      VIEW-AS ALERT-BOX INFORMATION BUTTONS OK TITLE "No Customer".
   END.
END.
```

Notes

- The current value of a sequence can be one of the following:
  - The initial value specified in the Data Dictionary
  - The last value set with either the CURRENT-VALUE statement or the NEXT-VALUE function
  - The Unknown value (?) if the sequence has exceeded its minimum or maximum and is not cycling
• Sequence values are stored in the database in which they are defined, and persist between each invocation of the CURRENT-VALUE statement or NEXT-VALUE function.

• You cannot invoke the CURRENT-VALUE function from within a WHERE clause. Doing so generates a compiler error. To use a result from the CURRENT-VALUE function in a WHERE clause, assign the result to a variable, then use the variable in the WHERE clause.

• You can use any combination of the NEXT-VALUE function, CURRENT-VALUE function, CURRENT-VALUE statement, and their dynamic versions. Use the dynamic version when you don’t know what the database name or sequence name is at run time.

• Be careful when accessing a database sequence with an alias that points to a different database than the one used when the alias was defined. If you supply an alias name to the CURRENT-VALUE function or the NEXT-VALUE function, only the database used to define the alias is referenced. In this case, it is preferable to use the DYNAMIC-CURRENT-VALUE function and DYNAMIC-NEXT-VALUE function instead of the CURRENT-VALUE function and NEXT-VALUE function, respectively.

See also CURRENT-VALUE statement, DYNAMIC-CURRENT-VALUE function, DYNAMIC-CURRENT-VALUE statement, DYNAMIC-NEXT-VALUE function, NEXT-VALUE function

CURRENT-VALUE statement

Resets the current integer value of a sequence defined in the Data Dictionary.

Syntax

```sql
CURRENT-VALUE ( sequence [ , logical-dbname ] ) = expression
```

**sequence**

An identifier that specifies the name of a sequence defined in the Data Dictionary.

**logical-dbname**

An identifier that specifies the logical name of the database in which the sequence is defined. The database must be connected. You can omit this parameter if the sequence name is unambiguous. If more than one connected database has a sequence with given name, then you must supply `logical-dbname`.

**expression**

An integer expression assigned as the current value of the specified sequence. If `expression` is outside the boundary set by the initial value (at one end) and the lower limit or upper limit (at the other end) for the sequence, the AVM returns an error, and the sequence value remains unchanged.

Example

The following example resets the current value of the NextCustNum sequence to the CustNum value of the last Customer record if that is a valid value for the sequence:
The user must have CAN-WRITE privileges on the _Sequence table to use the CURRENT-VALUE statement.

The value of a sequence set by the CURRENT-VALUE statement persists in the database until the next CURRENT-VALUE statement or NEXT-VALUE function is invoked for the sequence, or until the sequence is deleted from the database.

You cannot set a sequence to the Unknown value (?).

You can use any combination of the NEXT-VALUE function, CURRENT-VALUE function, CURRENT-VALUE statement, and their dynamic versions. Use the dynamic version when you don’t know what the database name or sequence name is at run time.

See also CURRENT-VALUE function, DYNAMIC-CURRENT-VALUE function, DYNAMIC-CURRENT-VALUE statement, DYNAMIC-NEXT-VALUE function, NEXT-VALUE function

---

r-curvl1.p

```plaintext
FIND LAST customer NO-LOCK.

IF Customer.CustNum < CURRENT-VALUE(NextCustNum) AND
    Customer.CustNum > 1000 THEN DO:
    MESSAGE "The value of NextCustNum has been changed to"
    Customer.CustNum VIEW-AS ALERT-BOX INFORMATION BUTTONS OK.
END.
ELSE
    MESSAGE "The value of NextCustNum remains"
    CURRENT-VALUE(NextCustNum) VIEW-AS ALERT-BOX INFORMATION BUTTONS OK.
```
Data types

The data type of a data element defines what kind of data the data element can store. ABL supports the following basic kinds of data types:

- ABL built-in primitive types, including mappings to corresponding .NET primitive types
- Object types, which include both ABL and supported .NET object types, including both built-in and user-defined class and interface types
- ABL handle-based objects
- ABL arrays, including one-dimensional arrays of ABL primitive types, ABL object types, or .NET object types

ABL primitive types (see Table 20) are built-in data types that can hold values with relatively simple content and that support relatively simple operations that can typically be applied using built-in ABL operands, such as arithmetic or relational operands (for example, the + Addition operator, or the EQ or = operator). The values for all ABL primitive types, other than the MEMPTR, BLOB, CLOB, and LONGCHAR, are limited in memory size to 32KB. MEMPTR and LONGCHAR variables can be any size, and BLOB and CLOB fields can be up to 1GB in size. Note that you can define BLOB and CLOB data types only for table or temp-table fields, and, unlike most other ABL primitive types, the operations they support do not have built-in ABL operands, but are available using built-in ABL functions (for example, the COPY-LOB statement).

You can use a primitive data type keyword in the following ABL syntax:

- DEFINE PARAMETER statement
- DEFINE PROPERTY statement
- DEFINE VARIABLE statement
- Fields of a table from an OpenEdge RDBMS using OpenEdge Architect or the Data Dictionary.
- Fields of a temp-table using the DEFINE TEMP-TABLE statement or methods of a Temp-table object handle.
- FUNCTION statement (return type)
- METHOD statement (return type)
- Parameter definition syntax (for a user-defined method or function)
**ABL object types** (see Table 21) are complex types that include class and interface types, and which function according to object-oriented principles. ABL supports a set of built-in object types and also allows you to create your own user-defined object types using the **CLASS statement** and **INTERFACE statement**. All ABL class types ultimately inherit from the ABL root class, **Progress.Lang.Object class**. Each object type encapsulates a set of data and behavioral elements (members). ABL class members can include implementations for data members, properties, and methods, including instance members that are available for access on any instance of that class and static members that are available for access using the class type itself, regardless if a class instance of the type exists. An interface type can define a common set of prototypes for methods, properties, and events that classes can implement. An ABL class can also be defined as abstract, which allows it to optionally define certain members as abstract. Abstract class members can be methods, properties, or events that are similar to interface member prototypes, but they can only be implemented by a class that derives from the abstract class. Aside from defining and implementing its own members, an ABL class can inherit members from another class and it must implement all member prototypes from interfaces that it implements and all abstract members from any abstract class that it inherits.

You can create instances of classes (**class-based objects**) at run time using the **NEW function** (classes), and you can reference each instance and its PUBLIC members using an **object reference**, which is an ABL data element defined to reference a specific object type. You can define an object reference for any kind of ABL data element that you can define as an ABL primitive type (except a database table field). However, you can define a field of a temp-table as an object reference to the ABL root class (**Progress.Lang.Object class**).

An object reference can reference the same class instance when it is defined as any of the following object types:

- The class type of the referenced class instance
- The interface type of any interface that the referenced class implements
- A class type (**subclass**) that is derived from the class type of the referenced class instance (if and only if the referenced class instance is an instance of the derived class type)

For more information on defining an ABL class type, see the **CLASS statement** reference entry. For more information on defining an ABL interface type, see the **INTERFACE statement** reference entry. For information on the built-in ABL class and interface types, see the “Class and Interface Reference” section on page 1851.

**.NET primitive types** (see Table 23) include data types that are built-into .NET languages that each language names in its own way (for example, the C# int and the Visual Basic Integer). .NET also aliases (maps) a standard set of object types (**.NET mapped object types**, for example, **System.Int32**) to these primitive types. All .NET languages can reference each such type as either the primitive type that the particular language supports or as the alias for the corresponding .NET object type that every language supports.

ABL also references both the .NET primitive types and their corresponding mapped object types by mapping each ABL primitive type to a given set of .NET primitive and object type mappings (see Table 23). Thus, ABL documentation refers collectively to both the .NET primitive types and the corresponding .NET mapped object types as **.NET mapped data types**.
Data types

.NET object types (see Table 21) include all class types (and their derivatives) that derive from the .NET root class, System.Object, and .NET interface types, which can inherit from other .NET interface types, but otherwise function for a class much like an ABL interface type. You can reference a .NET object type like an ABL object type, by using an ABL object reference defined as that object type, or by referencing members of a .NET class. .NET object types also consist of two basic kinds of types:

- **Value types** — Objects that .NET creates, passes, and assigns by value. Value type objects all inherit from the .NET class, System.ValueType. In ABL, when you access a value type from .NET, you access a new copy of the object that is separate from the one that is maintained by .NET. If you then change object data in ABL, these changes do not appear in any copy of the object maintained by .NET. In addition, the ABL object reference to the ABL copy of the object has no affect on the .NET garbage collection of any .NET copy of the object.

- **Reference types** — Objects that .NET creates, passes, and assigns by reference. In ABL, when you access a .NET reference type, you access the same copy of the object that is maintained by .NET. If you then change object data in ABL, these changes also appear in .NET, because .NET references the same object. In addition, the ABL object reference is counted as a reference to the object for .NET garbage collection.

ABL also provides limited support for .NET abstract classes and .NET generic types. A .NET abstract class is similar to an ABL abstract class. A generic type has a type definition that can function as one of several different types, depending on type parameters used to complete the effective type name. .NET generic types are briefly described further in this entry. For more information on the basic kinds of .NET object types that ABL supports, see the notes section of this reference entry. OpenEdge also provides a set of built-in .NET class and interface types to support access to .NET object types. For information on the built-in .NET class and interface types, see the “Class and Interface Reference” section on page 1851.

Within certain restrictions, an ABL class can inherit from a .NET class and implement .NET interfaces, similar to inheriting from an ABL class or implementing an ABL interface, respectively. When an ABL class inherits from a .NET class, any of its methods that override methods in the .NET class hierarchy can be called polymorphically on the .NET super class from both ABL and .NET. As a result, any ABL class that inherits from a .NET class becomes an ABL-derived .NET class. In fact, when an ABL-derived .NET class is instantiated in an ABL session, an instance with a corresponding .NET class type is also instantiated in the .NET context with reference to any ABL-overridden methods.

Similarly, when an ABL class implements a .NET interface, all of the ABL-implemented properties and methods can be called polymorphically on the interface type from both ABL and .NET. As a result, any ABL class that implements a .NET interface becomes an ABL-extended .NET class. In fact, when an ABL-extended .NET class that implements .NET interfaces is instantiated in an ABL session, an instance with a corresponding .NET class type is also instantiated in the .NET context with reference to the ABL-implemented properties and methods that might be accessed from .NET on each of the implemented interface types.

**Note:** An ABL-derived .NET class is also considered an ABL-extended .NET class. However, an ABL-extended .NET class that only implements .NET interfaces is not an ABL-derived .NET class. Thus, when OpenEdge documentation refers to an ABL-extended .NET class, it can also (but not necessarily) be referring to an ABL-derived .NET class.
**ABL handle-based objects** (see Table 21) include a set of complex, weakly-typed objects, some of which ABL provides as built-in system objects (such as, the **SESSION system handle**), and others that ABL supports as a pre-defined set of objects that you can create as needed (such as, a **FRAME widget** or a record buffer). Handle-based objects exist independently and have no inheritance hierarchy like class-based objects. However, like class-based objects, handle-based objects have members consisting of a set of attributes (data) and methods (behavior). Depending on the object, you can create a handle-based object as a compile-time (static) object using an appropriate **DEFINE** statement or as a run-time (dynamic) object using an appropriate **CREATE** statement or other executable statement. You can reference system objects using the built-in system handle (keyword) pre-defined for them. You can reference static handle-based objects by name, using appropriate syntax for each type, and you can reference dynamic or static handle-based objects using a common primitive data element known as a handle, which you define as the **HANDLE** data type. Because of the weak typing of these objects, you can reference all static and dynamic handle-based objects that you define or create using the same handle. ABL also provides some system handles that provide access to particular types of pre-defined handle-based objects that are in a given state (such as, the **CURRENT-WINDOW system handle** for accessing a particular **WINDOW widget**).

**ABL arrays** (see Table 21) are limited to one dimension and can include elements of any primitive or object type that you can define for a variable (see the **DEFINE VARIABLE** statement reference entry). ABL also provides support for mapping ABL arrays to one-dimensional .NET array objects of the same element type. This means that while you can access all .NET arrays as class instances, you can also make direct array assignments and pass routine parameters between ABL arrays and equivalent one-dimensional .NET array objects. This also includes .NET arrays whose elements are .NET mapped data types (referred to as **.NET arrays of mapped types**), where assignments to or from ABL arrays work using the rules of implicit data type mapping. The element types supported for a .NET array of mapped types are identical to the .NET data types that ABL implicitly maps to ABL primitive types (see Table 23). For more information on support for both ABL arrays and .NET arrays, see the notes section of this reference entry.

Table 20 describes the primitive types supported in ABL.

### Table 20: ABL primitive types

<table>
<thead>
<tr>
<th>Primitive type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>BLOB</td>
<td>BLOB (Binary Large OBject) specifies a database table or temp-table field that contains a BLOB locator, which points to the associated BLOB data stored in the database. You must use a MEMPTR to manipulate the binary contents of a BLOB field in ABL.</td>
</tr>
<tr>
<td>CHARACTER</td>
<td>CHARACTER data consists of numbers, letters, and special characters.</td>
</tr>
<tr>
<td>CLOB</td>
<td>CLOB (Character Large OBject) specifies a database table or temp-table field that contains a CLOB locator, which points to the associated CLOB data stored in the database. You must use a LONGCHAR to manipulate the character contents of a CLOB field in ABL.</td>
</tr>
<tr>
<td>COM-HANDLE</td>
<td>A COM-HANDLE is a handle to a COM object (ActiveX Automation object or ActiveX Control).</td>
</tr>
<tr>
<td>Primitive type</td>
<td>Description</td>
</tr>
<tr>
<td>-------------------</td>
<td>-----------------------------------------------------------------------------</td>
</tr>
<tr>
<td>DATE</td>
<td>DATE fields contain dates.</td>
</tr>
<tr>
<td>DATETIME</td>
<td>DATETIME data has two parts: an ABL date and an ABL time. The unit of time is milliseconds from midnight.</td>
</tr>
<tr>
<td>DATETIME-TZ</td>
<td>DATETIME-TZ data has three parts: an ABL date, an ABL time, and an integer representing the time zone offset from Coordinated Universal Time (UTC). The unit of time is milliseconds from midnight. The unit of time zone offset is minutes.</td>
</tr>
<tr>
<td>DECIMAL</td>
<td>DECIMAL data consists of decimal numbers up to 50 digits in length including up to 10 digits to the right of the decimal point.</td>
</tr>
</tbody>
</table>
| HANDLE            | A HANDLE is a pointer to an ABL handle-based object. This can be a compile-time defined static object or a run-time defined dynamic object.  
**Note:** HANDLE and WIDGET-HANDLE can be assigned to each other and used interchangeably. WIDGET-HANDLE is supported only for backward compatibility. |
| INT64             | An INT64 consists of 64-bit data (whole numbers).                           |
| INTEGER           | An INTEGER consists of 32-bit data (whole numbers).                        |
| LOGICAL           | LOGICAL data evaluates to TRUE or FALSE (or YES or NO).                    |
| LONGCHAR          | A LONGCHAR consists of CHARACTER data that is not limited to 32K in size. You can use a LONGCHAR to manipulate the character contents of a CLOB database or temp-table field in ABL. |
| MEMPTR            | A MEMPTR contains a sequence of bytes in memory. You can use a MEMPTR to manipulate the contents of a BLOB database or temp-table field in ABL. |
| RAW               | RAW data can be any kind of data, even data from non-OpenEdge databases. It is not converted in any way. |
| RECID             | A RECID is a unique internal identifier for a record within a single database storage area.  
**Note:** RECID is supported mainly for backward compatibility. For most applications, use ROWID instead. |
| ROWID             | A ROWID is a unique internal identifier for a record within a single database storage area. |
| WIDGET-HANDLE     | A WIDGET-HANDLE is a pointer to an ABL handle-based object.  
**Note:** HANDLE and WIDGET-HANDLE can be assigned to each other and used interchangeably. WIDGET-HANDLE is supported only for backward compatibility. |

Table 21 describes the non-primitive (complex) types supported in ABL.
### Table 21: ABL complex types

<table>
<thead>
<tr>
<th>Complex type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Array</strong></td>
<td>An ABL array type is a complex type that specifies a one-dimensional array of elements of the same scalar data type with a 1-based index, where a <em>scalar</em> data type is any data type that is not, itself, an array. The elements of an ABL array can contain scalars of any supported ABL primitive type, any ABL object type, or any .NET object type (other than a .NET mapped object type). The type definition for an ABL array is specified by the type definition for the array element with the addition of the EXTENT option (or with the Extent option selected in OpenEdge database tools). Thus, you can define an ABL array data element using similar features and syntax used to define primitive and object-type data elements. However, you cannot define ABL array types for the BLOB or CLOB primitive type. Also, note that unlike ABL arrays, .NET arrays are objects with an object type, just like any other .NET type. However, all .NET array object types derive from the <code>System.Array</code> class (a reference type), and you can create and access .NET arrays using public members of <code>System.Array</code>. Also, .NET arrays can be multi-dimensional and typically have a 0-based index. In .NET, the object type name of an array object is the object type name of its array elements appended with a set of square brackets (<code>[]</code>) with an embedded comma added for each additional dimension in the array. For example, <code>System.Drawing.Point[]</code> is a one-dimensional array object type and <code>System.Drawing.Point[,]</code> is a two-dimensional array object type. .NET languages support syntax for additional kinds of array objects, including jagged arrays. For more information on .NET array syntax, see the “Arrays Tutorial” in the C# Programmer’s Reference on MSDN. In ABL, you must also enclose any .NET array object type name in double-quotes in order to handle the square brackets and any commas, which are special characters in ABL names, for example, &quot;System.Drawing.Point[].&quot; For more information on specifying array types, see the Type-name syntax reference entry.</td>
</tr>
</tbody>
</table>
Table 22 lists the default data formats and initial values for ABL primitive and object types.

<table>
<thead>
<tr>
<th>Complex type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>[CLASS ]</td>
<td>Specifies an object type, where object-type-name can specify any ABL or .NET object type name. (CLASS is an optional keyword that can be used in ABL syntax to define an object reference to the specified object type.) You can specify an object-type-name in order to:</td>
</tr>
<tr>
<td></td>
<td>• Define a user-defined ABL class or interface type, or an ABL-derived .NET class type</td>
</tr>
<tr>
<td></td>
<td>• Define an object reference to an instance of a specified ABL or .NET class or interface type (built-in or user-defined)</td>
</tr>
<tr>
<td></td>
<td>• Cast an object reference from a specified object type to a derived or otherwise extended type</td>
</tr>
<tr>
<td></td>
<td>• Reference static members of a specified ABL or .NET class type</td>
</tr>
<tr>
<td></td>
<td>For more information on referencing and specifying object type names, see the Type-name syntax reference entry.</td>
</tr>
<tr>
<td>Handle-based object</td>
<td>A handle-based object has a built-in and inherent ABL type that provides data and behavior of varying complexity depending on the purpose of the object. A few examples include:</td>
</tr>
<tr>
<td></td>
<td>• Visual representation objects (widgets), such as buttons (defined using the DEFINE BUTTON statement, rectangles (defined using the DEFINE RECTANGLE statement), or data-representation widgets, such as a fill-ins (defined as part of the DEFINE VARIABLE statement or DEFINE PARAMETER statement) or browses (grid-like widgets defined using the DEFINE BROWSE statement)</td>
</tr>
<tr>
<td></td>
<td>• Data objects, such as temp-tables (defined using the DEFINE TEMP-TABLE statement), ProDataSets, (defined using the DEFINE DATASET statement), and related data objects, such as queries (defined using the DEFINE QUERY statement)</td>
</tr>
<tr>
<td></td>
<td>• Streams (defined using the DEFINE STREAM statement), which are used for reading and writing sequential data, such as text files</td>
</tr>
<tr>
<td></td>
<td>• Procedure objects (each defined as a file of ABL source code and created at run time using the RUN statement)</td>
</tr>
<tr>
<td></td>
<td>• Socket and server socket objects (created at run time using the CREATE SOCKET statement and CREATE SERVER-SOCKET statement)</td>
</tr>
<tr>
<td>Note:</td>
<td>While each type of handle-based object is unique, because of their weak typing, you can reference all such objects using the same primitive type, HANDLE (see Table 20).</td>
</tr>
<tr>
<td></td>
<td>For more information on each type of handle-based object, see the reference entry for its type in the “Widget Reference” section on page 1143 or the “Handle Reference” section on page 1189, and see the reference entry for its respective DEFINE, CREATE, or other instantiating executable statement.</td>
</tr>
</tbody>
</table>
Table 22: Default ABL data type initial values and display formats

</table>

1. You cannot display a BLOB, CLOB, MEMPTR, RAW, or ROWID value directly. However, you can convert a MEMPTR, RAW, or ROWID value to a character string representation using the STRING function and display the result. You can also convert a BLOB to a MEMPTR, and then use the STRING function. A MEMPTR or RAW value converts to a decimal integer string. A ROWID value converts to a hexadecimal string, "0x\(\text{hexdigits}\)," where \(\text{hexdigits}\) is any number of characters "0" through "9" and "A" through "F". You can display a CLOB field by converting it to a LONGCHAR, and displaying the LONGCHAR using the VIEW-AS EDITOR LARGE phrase only.

2. If you display a class instance using the MESSAGE statement, ABL automatically invokes the Tostring( ) method (provided by the Progress.Lang.Object class) on the object reference. To display a class instance in a frame (for example, using the DISPLAY statement), you must first explicitly convert the object reference to a displayable type using the INT64 function, the INTEGER function, the STRING function, or the Tostring( ) method.

3. You cannot use the INITIAL option to specify an initial value for this data type as part of the definition of a variable, procedure parameter, or class-based property.
For more information on using the built-in ABL primitive types, see *OpenEdge Getting Started: ABL Essentials* and the Web paper, *ABL Data Types in OpenEdge Release 10*.

As noted previously in this entry, ABL supports references to .NET types in two basic ways:

1. You can make direct and explicit reference to .NET object types using similar syntax that is supported for referencing ABL user-defined class and interface types. For supported .NET object types, this includes both the instantiation of a .NET class in ABL and the derivation of the .NET class by an ABL user-defined class (ABL-derived .NET class), and it includes the implementation of supported .NET interfaces by an ABL user-defined class (ABL-extended .NET class). To integrate the .NET class hierarchy with the ABL class hierarchy, ABL views `System.Object` as an immediate subclass of the ABL root class (`Progress.Lang.Object` class). In this way, you can manage .NET object types in ABL using many of the same mechanisms that you use for managing ABL class and interface types. However, you must observe the following limitations:

   - You cannot directly reference any .NET object type that is supported as a .NET mapped data type, except to define a .NET array of such types. You can only reference .NET mapped data types as their equivalent ABL built-in primitive types. For more information on .NET mapped data types, see the immediately following Step 2.
   - You cannot use `System.Threading.Thread`, or any derived class—ABL is single-threaded.
   - You cannot use `System.MulticastDelegate`, or any derived class (otherwise referred to as delegates) to provide handlers for .NET events. ABL provides its own event handling model for .NET events. For more information, see the “Class Events Reference” section on page 1953.
   - You cannot define an ABL interface that inherits from a .NET interface.
   - ABL imposes additional requirements on the .NET classes you can extend and the .NET interfaces you can implement in an ABL user-defined class. For more information, see the CLASS statement and INTERFACE statement reference entries.

   For more information on the requirements for accessing .NET object types, see the notes section of this reference entry and *OpenEdge Development: GUI for .NET Programming*.

2. You can make implicit access to all .NET primitive types and their associated mapped object types by using the ABL built-in primitive types that are mapped to them. Because .NET mapped object types and .NET primitive types, together, represent the complete set of .NET mapped data types, the implicit mapping between .NET mapped data types and ABL primitive types allows you to access .NET method parameters, fields (data members), and properties using the corresponding ABL primitive types without direct reference to their .NET data type equivalents. In fact, ABL does not allow you to directly reference either the .NET primitive types or the .NET mapped object types as scalars without raising a compile-time error. (The exception is when defining a .NET array of mapped types. For more information, see the notes section of this reference entry.)

Table 23 shows the implicit mappings supported between .NET mapped data types and ABL built-in primitive types, showing the corresponding primitive types from C#.

1. An ABL INTEGER is a 32-bit number. Thus, it can hold values that are too big to store in a .NET System.Byte, System.SByte, System.Int16, or System.UInt16. Therefore, AVM raises a run-time error if an incompatible value is assigned.

2. If you pass a negative ABL data type to an unsigned data type, the ABL virtual machine (AVM) raises a run-time error.

3. The range of values for a .NET System.Decimal and the range of values for an ABL DECIMAL are not equivalent. In particular, an ABL DECIMAL can be a much larger positive number or a much smaller negative number than a .NET System.Decimal can represent, and a .NET System.Decimal can represent a positive or negative number with much higher precision (with more significant digits to the right of the decimal point) than an ABL DECIMAL can represent. Therefore, the AVM raises a run-time error if you assign too large or too small of an ABL DECIMAL value to a .NET System.Decimal. If you assign too precise a .NET System.Decimal to an ABL DECIMAL, with too many significant digits to the right of the decimal point, ABL truncates the least significant digits necessary to represent the value as an ABL DECIMAL.

4. The .NET default match for this ABL primitive type when passed as an overloaded method parameter, when passed to a System.Object parameter, when used to define an overridden .NET method, when used to implement (or override) a .NET interface (or abstract) method, property, or event, or when converted using the BOX function, all without a specified AS data type indication. For more information on AS data types, see the following paragraphs and Table 24.

5. An ABL INT64 is a 64-bit number. Thus, it can hold values that are too big to store in a .NET System.UInt32. Therefore, AVM raises a run-time error if an incompatible value is assigned.

6. An ABL DECIMAL can represent a much larger number than a System.UInt64. Therefore, AVM raises a run-time error if an incompatible value is assigned.

7. An ABL DECIMAL represents numbers up to 50 digits long. As a result, an ABL DECIMAL value cannot represent the full range of values for a .NET System.Double or System.Single. Therefore, AVM raises a run-time error if an incompatible value is assigned. Also, an ABL DECIMAL can lose precision when it is represented by a .NET System.Double or System.Single.
Thus, instead of using an object reference to the corresponding .NET mapped object type, you must provide or access all .NET primitive (or mapped object type) values for .NET methods, data members, and properties as ABL primitive types. Similarly, when you reference any data element or value defined as a .NET mapped data type, ABL evaluates the .NET value to its corresponding ABL primitive value. ABL checks for .NET/ABL type compatibility at compile time, except in rare cases where data type narrowing is allowed, in which case the AVM checks for data overflow or underflow at run time.

Note: To access all other .NET value types in ABL except mapped data types (for example, System.Drawing.Size), you can and must use object references to the value type objects.

.NET supports a concept known as boxing. Boxing is the process of converting a value type (such as a C# int or .NET System.Int32) to a reference type object. Boxing a value type wraps its value inside a System.Object. Unboxing extracts the value from the System.Object as the original value type. In .NET, boxing and unboxing between a value type and a System.Object occurs during assignment or parameter passing.

So, in addition to implicitly mapping its native primitive types to their corresponding .NET mapped data types, ABL also supports boxing between its primitive or array types and a .NET System.Object or array object. ABL performs boxing operations automatically in two cases:

- When you assign values between a .NET System.Object or one-dimensional array object and a compatible ABL primitive or array type
- When you pass parameter values for .NET methods and constructors between a .NET System.Object or one-dimensional array object and a compatible ABL primitive or array type

However, as described further in this entry, ABL does not support automatic boxing operations when passing parameters to ABL routines.

When ABL does automatic boxing that involves ABL primitive types or arrays of elements containing primitive types, it also does implicit conversion between these types and the corresponding .NET mapped types (see Table 23). For example, if you assign an ABL INTEGER to a System.Object, ABL converts the ABL INTEGER to a System.Int32, which the System.Object accepts as a subclass value. Similarly, if you assign an ABL INTEGER array to a System.Object, ABL converts the ABL INTEGER array to a “System.Int32[]”, which the System.Object accepts as a subclass value. The same occurs when you pass an ABL INTEGER or INTEGER array to a System.Object INPUT parameter of a .NET method.

In reverse, when you assign an appropriate System.Object to an ABL INTEGER or INTEGER array, ABL unboxes the System.Object by determining the .NET mapped type that the System.Object represents, converts that value to its equivalent ABL primitive or primitive array value, and attempts to assign the result to the ABL INTEGER or INTEGER array (which is validated at run time). For example, if the System.Object represents the System.Decimal subclass and you are assigning it to an ABL INTEGER, ABL converts the System.Decimal value to an ABL DECIMAL and attempts to assign it to the ABL INTEGER.

8. This ABL CHARACTER mapping supports a single Unicode character.
9. When the value comes from .NET, ABL converts from System.String to either CHARACTER or LONGCHAR, depending on the length of the character string. When the value comes from ABL, System.String accepts values from either CHARACTER or LONGCHAR.
In a similar manner, ABL also does automatic boxing directly between compatible ABL arrays and one-dimensional .NET array objects. For example, if you assign or pass .NET method parameters between a "System.Windows.Forms.Button[]" array object and an ABL array of System.Windows.Forms.Button elements, ABL automatically does the required boxing and unboxing to convert between the different array types. A similar boxing and unboxing operation occurs between an ABL primitive array and a compatible .NET array of mapped types, for example, between an ABL array of INTEGER and a .NET "System.Int16[]" array object. For more information on boxing and unboxing between ABL and .NET arrays, see the notes section in this reference entry on working with .NET arrays.

However in the following four ABL contexts, automatic ABL boxing or unboxing is either not supported or might not be supported as you require:

- When you use a System.Object directly in an expression, ABL does not unbox the System.Object into a compatible ABL primitive type.
- When you assign an ABL primitive value (or primitive array) to a System.Object and the ABL primitive type maps to multiple .NET data types, it automatically boxes the ABL primitive value (or primitive array elements) as the default matching .NET mapped object type, which might not be the .NET data type mapping that you require.
- ABL does no automatic boxing or unboxing when you pass an ABL primitive or array type to a compatible .NET object parameter of an ABL routine (ABL method, procedure, or user-defined function). Similarly, ABL also does no automatic boxing or unboxing when you pass a compatible .NET object argument to the ABL primitive or array parameter of an ABL routine.
- ABL does no boxing or unboxing of array elements when you box or unbox an ABL array. For example, ABL cannot assign between a "System.Object[]" and an ABL INTEGER array, because it does not handle boxing and unboxing between the corresponding System.Object and the INTEGER array elements. For more information on ABL support for array assignments, see the notes section of this reference entry.

When you use a System.Object directly in an expression, ABL raises a compile-time error because ABL does not support automatic unboxing of a System.Object in an expression. Instead, you can use the ABL built-in UNBOX function in the expression to explicitly unbox the value. This function accepts the System.Object as input and returns an ABL primitive value that is equivalent to the .NET mapped object type value (subclass) represented by the specified .NET System.Object instance.

When you assign an ABL primitive value or primitive array to a System.Object, ABL always boxes the value or array into a particular .NET mapped type or array of mapped types, which might not be the .NET type you want. In Table 23, several ABL primitive types implicitly map to more than one .NET mapped data type. For each ABL primitive type that maps to multiple .NET data types, ABL uses one of these mappings as the .NET default match for the ABL primitive type (indicated by a footnote4 in Table 23). Thus, when you assign an ABL primitive value or primitive array to a System.Object, ABL automatically boxes the value or array using the .NET default match for the specified ABL data type. For example, by default an INTEGER automatically boxes as a System.Int32, and an INTEGER array automatically boxes as a "System.Int32[]".
However, you can explicitly box the ABL value or array using a .NET mapped type other than the default match with the ABL built-in BOX function. This function accepts an ABL primitive value or array as input and, by default, returns a boxed .NET type according to the .NET default match for the ABL data type of the input value or array. In order to box the value using a mapped type other than the .NET default match, you can pass an ABL keyword as a string to the function that indicates the explicit .NET type you want to use. For example, an ABL DECIMAL value can represent both a .NET System.Decimal (the default match) and a System.Double (among other possible types). If you need to box the ABL DECIMAL as a .NET System.Double, you can explicitly indicate this to the BOX function. Similarly, if you need to box an ABL DECIMAL array as a "System.Double[]", you can use the same indication.

**Note:** When you unbox a System.Object using the UNBOX function, you cannot similarly specify a particular ABL primitive or primitive array type as the result. ABL always unboxes any System.Object using the default matching ABL type.

Another case for which you must use the BOX function or the UNBOX function is when you pass parameters between compatible ABL primitive or array types and .NET object types in the parameters of ABL methods, procedures, and user-defined functions. ABL raises a compiler error if you try to pass these types to each other directly in ABL routine parameters. Appropriate use of the BOX function or UNBOX function allows this type of parameter passing to occur without a compile-time error. Note, again, that ABL does support the automatic boxing and unboxing of .NET objects in parameter passing for .NET method calls.

Similarly, three additional cases exist (other than the need for explicit boxing) where you must specify the .NET data type mapping you want for a given ABL primitive type:

- When a method parameter is overloaded by multiple implicit .NET data type mappings for a passed ABL primitive type. You must specify the exact .NET data type when you pass the parameter to the method.

- When you override a method inherited from a .NET class, or when you implement (or override) a .NET interface (or abstract) method, property, or event, and the types of any associated parameters, properties, or return values are .NET mapped data types. You must specify the exact .NET data type in the definition of each .NET mapped parameter, property, and return value.

- When you pass an ABL primitive value (not an array) to a .NET method or constructor parameter that is a System.Object, and you want the result to be a .NET mapped type other than the default match. You must indicate the explicit mapped type on the passed ABL primitive argument. A common use case is the SetValue() method of the System.Array class, which sets the value of a .NET array element. If the .NET type of the array element is other than the default match, you must indicate the .NET mapped type for the value parameter to match the array definition.

- When you reference a constructed .NET generic type (described further in this entry) using type parameters that include a .NET mapped type.

To indicate a non-default .NET mapped type in the previous cases where you want an explicit mapped type to be used, the syntax for the following ABL elements allows you to specify an appropriate ABL keyword:

- BOX function

- DEFINE PROPERTY statement
Data types

- METHOD statement
- Parameter definition syntax
- Parameter passing syntax

This keyword is referred to as an AS data type, because you specify it for a passed parameter using the AS option. So, for example, when you override a .NET method, you must explicitly specify .NET data type for each .NET mapped parameter, property, or return type. If the .NET data type is a default match, you must simply use the matching ABL data type. Otherwise, you must indicate the appropriate AS data type keyword for the data type of the method parameter, return type, or property definition.

Table 24 lists each explicit .NET data type mapping for a given ABL primitive type. For each listed .NET data type, you indicate this explicit mapping either by using the corresponding ABL primitive type (for a default match) or by using the appropriate option to specify the AS data type that corresponds to the explicit .NET data type you want to map. For more information on specifying the AS data type option when using the BOX function or when calling overloaded .NET methods, see the reference entries for the BOX function and Parameter passing syntax in this book. For more information on specifying AS data types when overriding a .NET method, or when implementing (or overriding) a .NET interface (or abstract) method, property, or event, see the METHOD statement, the DEFINE PROPERTY statement, the DEFINE EVENT statement, or the Parameter definition syntax reference entry, as appropriate.

Note: The AS data types in Table 24 represent some different data types than you can specify using the AS option to pass a COM method parameter. For more information on passing COM method parameters, see the “Syntax for accessing COM object properties and methods” section on page 1278.

</table>
A .NET generic type is a class or interface defined so that it functions as one of several different types, depending on how you reference its type name. A reference to a .NET generic type name includes one or more type parameters, each of which specifies a data type that the generic type can use in its implementation. When you reference the generic type name in ABL, you substitute a specific data type for each type parameter defined for the generic type. This reference then identifies the generic type as a constructed type. The notation for a generic type that you see in .NET documentation or in a class browser, where the type parameters are not resolved, is called an open type. An open type reference contains only placeholders for the parameters in the type name, such as <T>, which defines the single parameter for the following generic type:

```
System.Collections.Generic.List<T>
```

In ABL, you can only reference a .NET generic type as a constructed type using a type name that has the following syntax:

**Syntax**

```
"namespace.object-name<type-parameter [ , type-parameter ] ...>"
```

The namespace is a .NET namespace and the syntax from object-name up to and including the right angle bracket (>) forms the dotNET-object-name as described in the Type-name syntax reference entry. The left and right angle brackets (<>) are the part of .NET generic type name references that enclose the type parameters, as shown in the previous example. Each type-parameter in the parameter list represents a placeholder for a specific .NET data type.

The number of type parameters and the data type that you can specify for each type-parameter in a constructed type reference depends on the generic type definition. However, you can never specify an ABL object type or an ABL-extended .NET class type as the data type of any type-parameter; it can only be a pure .NET type. The quotes are required in order to allow for the angle brackets and any spaces in the type name.
The definition for each type-parameter in a .NET generic type definition can specify constraints that determine the .NET types you can substitute for a given parameter when you reference the constructed type. If these constraints on a type-parameter allow you to specify one or more .NET mapped types, you must specify an appropriate explicit mapping for each such type when you specify the type-parameter in ABL, as described in Table 24.

For example, to define an object reference to a System.Collections.Generic.List<T> that is constructed as a list of System.Int16, you might use the following ABL statement:

```
DEFINE VARIABLE shortList AS
   CLASS System.Collections.Generic.List<SHORT> NO-UNDO.
```

You can also reference an array of a generic type and define generic types with a type parameter that is an array. For more information, see the information on .NET arrays in the notes of this reference entry.

You can use a .NET generic type in all the same contexts as any other .NET type except to define an ABL class that:

- Inherits from a .NET generic class
- Implements a .NET generic interface

Also, while you can cast an object reference to a .NET generic type using the CAST function, you cannot cast to a .NET generic type using the DYNAMIC-CAST function.

For more information on how to identify .NET generic types and understand the constraints on their type parameters, see the .NET documentation on MSDN. For more information on working with .NET generic types in ABL, see OpenEdge Development: GUI for .NET Programming.

**Notes**

- ABL provides built-in data types, built-in class data types, and user-defined class data types. References to built-in data types follow these rules:
  - Like most other keywords, references to specific built-in data types appear in all UPPERCASE, using a font that is appropriate to the context. No uppercase reference ever includes or implies any data type other than itself.
  - Wherever integer appears, this is a reference to the INTEGER or INT64 data type.
  - Wherever character appears, this is a reference to the CHARACTER, LONGCHAR, or CLOB data type.
  - Wherever decimal appears, this is a reference to the DECIMAL data type.
  - Wherever numeric appears, this is a reference to the INTEGER, INT64, or DECIMAL data type.

References to built-in class data types appear in mixed case with initial caps, for example, Progress.Lang.Object. References to user-defined class data types appear in mixed case, as defined for a given application example.

- INT64 support applies to all of the ABL built-in methods and functions that take integer-expression parameters. That is, integer-expression parameters can be either INT64 expressions or INTEGER expressions.
• Starting with Release 10.1B, all intermediate calculations are carried out in 64-bit arithmetic. For example, 2,000,000,000 * 100 / 100 gives the correct result whether the target field is INTEGER or INT64. However, although 2,000,000,000 * 100 does not cause an overflow, you must assign the result to an INT64 field. If you assign it to an INTEGER field, the AVM generates a run-time error.

• In Version 9.0, when you copy one MEMPTR (M1) to another MEMPTR (M2), only the MEMPTR address is copied and both MEMPTRs point to the same memory location (L1). You can change the data in the single memory location and both MEMPTRs will point to the changed data. To clear memory after using the MEMPTRs, you can SET-SIZE = 0 on just one of the MEMPTRs.

Starting with Version 9.1, when you copy one MEMPTR (M1) to another MEMPTR (M2), the data that M1 points to is also copied. Therefore, MEMPTR M1 points to memory location L1, and MEMPTR M2 now points to memory location L2 which contains a copy of the data in L1. You must change the data in both memory locations if you want both MEMPTRs to reflect the change. To clear memory after using the MEMPTRs, you must execute SET-SIZE = 0 on both MEMPTRs to be sure that both memory locations are cleared.

• Since RAW variables are limited in size to 32K and MEMPTR variables are not limited in size, if a MEMPTR with a size greater than 32K is copied to a RAW variable, the AVM generates an error.

• Both a primitive type or object type can be defined as an array. Use the EXTENT option when defining or creating a field, variable, or object to establish an array. For example:

```
DEFINE VARIABLE someIntArray AS INTEGER EXTENT 4.
```

The variable someIntArray is now defined as an array of four integers. Since the size is fixed at 4, this is a determinate array. You can also define an indeterminate array by omitting the constant integer value after EXTENT. In this case, the number of elements in the array is undefined.

To refer to an individual element in an array, enclose the INTEGER index (subscript) using bracket syntax. This is known as a subscripted array reference. For example:

```
```

Here, 2 references the second element in the INTEGER array.

Arrays can also be manipulated as a whole for array-to-array deep copy operations and to pass or return parameters. By omitting the brackets, a reference to the field, variable, or object name is a reference to the entire array. This is called an unsubscripted array reference. For example:

```
ASSIGN someIntArray = anotherIntArray.
```

Here, each element of the anotherIntArray will be copied into the corresponding element of the someIntArray. This is called a deep copy. Note that unsubscripted array references
are not supported in expressions or comparison operations. For more information on array assignments, see the Assignment (=) statement reference entry.

- ABL supports access to the following kinds of .NET object types:
  - **Classes** — Viewed and managed like ABL classes with support for additional features that are unique to .NET classes, such as inner classes and indexers for indexed properties. For information on accessing instances of .NET classes, see the Class-based object reference entry.
  - **Interfaces** — Viewed and managed as ABL interfaces with support for additional features that are unique to .NET, such as inner interfaces.
  - **Structures** — Viewed and managed similar to ABL classes. Structure types are supported using syntax native to each .NET language, for example, using the struct keyword in C# and C++. For information on accessing instances of .NET structures, see the Class-based object reference entry. The essential difference between .NET structures and most other .NET classes is that structures inherit from System.ValueType and are therefore value types. Thus, all structures are passed within .NET, and between ABL and .NET, by value. However within ABL, structure objects are passed, like all other class instances, by reference. Therefore, when you access a structure from .NET, you reference a copy of the object in ABL that is separate from the object in .NET, and when you pass an ABL reference to a structure back to .NET, .NET gets a copy of the object that is separate from the object that is referenced in ABL. Structures therefore have different object management requirements in ABL than reference type objects. For more information, see the information on ABL support for value types in OpenEdge Development: GUI for .NET Programming.
  - **Enumerations** — Unique to .NET, enumerations are classes that correspond to a named set of constant values with a single underlying data type. Each of these constant values corresponds to a member of a given enumeration class. Each .NET language allows you to define and reference enumeration members using its own syntax. ABL also provides syntax that allows you to reference .NET enumerations as object types. For more information, see the Enumeration member access reference entry. Enumerations inherit from the System.Enum structure, which inherits from System.ValueType. Thus, like structures, enumerations are value types that are passed by value between .NET and ABL. However, unlike .NET languages that can view enumerations as values, ABL views enumerations only as objects that are passed by reference, like any other class instance. Enumerations therefore have similar object management requirements to structures in ABL. For more information, see the information on ABL support for value types in OpenEdge Development: GUI for .NET Programming.

You can instantiate .NET class or structure instances using the NEW function (classes), as with any ABL class. However, you cannot create an enumeration object. ABL can only reference enumeration objects that have already been defined in .NET. For information on specific .NET object types, see the documentation provided by the vendor for that object type.

- ABL supports widening relationships between certain ABL data types. Widening allows you to pass an argument to a method parameter that has a different data type than the parameter, depending on the data flow (INPUT or OUTPUT). Thus, the target of the data flow can be a different data type if it can hold the largest value provided by the source of
the data flow. When passing .NET method parameters or getting and setting .NET property values, ABL supports additional widening relationships between the ABL data type being passed and the .NET data type of the parameter. For more information, see the description of widening for .NET parameters in the Parameter passing syntax reference entry.

**Note:** These widening relationships do not apply to method return values. Methods return values with the exact data type defined for the method return value.

• A .NET array is an object that extends the System.Array class. You can access a .NET array in ABL using an object reference, like any other object. Thus, in ABL, you can access all .NET arrays, of all dimensions, whose element type is either an ABL-supported .NET object type (such as System.Windows.Forms.Form) or a .NET mapped data type (such as System.Int16 or C# short). You can also create .NET arrays directly in ABL by creating instances of the System.Array class. Note that while you cannot explicitly define a variable as a System.Int16, ABL does allow you to define a .NET array where the element type is a System.Int16 (or any other mapped object type). .NET arrays have the following class hierarchy in ABL, in order of derivation from the ABL root class:

a) Progress.Lang.Object
b) System.Object
c) System.Array
d) Any array class of a specified element type, for example, "System.Int32[]", which specifies a one-dimensional array of System.Int32 elements

You can define references to .NET arrays or ABL arrays (extents) of .NET array references:

```abl
```

You can also define references to arrays of a generic type or to generic types that have type parameters that are arrays. For example:

```abl
DEFINE VARIABLE shortListArrayExt AS CLASS "System.Collections.Generic.List<SHORT>" EXTENT 3 NO-UNDO.
```
Because all .NET array objects inherit from System.Array, you can access any .NET array object using the members of the System.Array class. To help create .NET array objects, OpenEdge provides a Progress.Util.TypeHelper class to specify the System.Type object needed for creating .NET array objects. For more information on working with .NET arrays, see the sections on accessing .NET arrays in OpenEdge Development: GUI for .NET Programming.

- If a .NET array is a multi-dimensional array, you can only work with it as a .NET array object, using the System.Array access mechanisms. However, if a .NET array is a one-dimensional array, you can work with it in two different ways:
  - Directly as a .NET array object
  - As an ABL array by directly assigning the .NET array to an equivalent ABL array, working with the resulting ABL array using ABL mechanisms, and directly assigning the reworked ABL array back to a .NET array

- An array assignment can occur between .NET and ABL arrays of compatible element types, either by direct assignment of one array to another using the Assignment (=) statement or the ASSIGN statement, or by passing array parameters to .NET methods using Parameter passing syntax. In these specific cases, ABL performs automatic boxing and unboxing between the compatible ABL and .NET array types. In general, you can assign an ABL or .NET array of .NET value types (such as System.Drawing.Size) only to another ABL or .NET array of identical value type elements. ABL makes an exception if the ABL array in the assignment is an array of primitive type elements (such as INTEGER), in which case ABL allows assignment to or from a compatible .NET array of mapped types (such as "System.Int32[]" or "System.Byte[]"). Otherwise (for reference types), elements of the target array must be identical to or higher in the class hierarchy than the elements of the source array. For example, you can assign an array of System.Windows.Forms.Form elements to an array of System.Object elements.

- While ABL does automatically box and unbox entire arrays for supported array assignments, ABL does not automatically box and unbox the elements of the source and target arrays. So, for example, you cannot assign an ABL array of INTEGER elements to a .NET array of System.Object elements ("System.Object[]").

- Given that array element types are compatible, how an array assignment works, depends on the system context (ABL or .NET) of the arrays involved. In general, if either or both the target or source of the assignment is an ABL array, this results in a deep copy of all the array elements from the source array to the target. If both the target and source of the assignment is a .NET array, as with any object assignment, this results in an object reference copy, where the target references the same array as the source. Other array interactions depend on the array type of the target.

Caution: Because assignment between a .NET array and an ABL array requires a deep copy, note the performance impact it might have on your application before coding this operation. For a .NET array, you might prefer to work directly with the object reference, and access individual elements using System.Array mechanisms.

- For a .NET and ABL array assignment where the target is an ABL array:
  - The source array must be another ABL array, a one-dimensional .NET array, or a System.Object whose type at run time is a one-dimensional .NET array, and the
element data type of the target array must be compatible with the element data type of the source, or the assignment raises an error. In general, the compatibility between source and target element types follows standard ABL rules for data type assignments, both within ABL and between ABL and .NET. For more information on data type compatibility for assignment and parameter passing, see the Assignment (=) statement and the Parameter passing syntax reference entry.

– If the target is an ABL array of System.Object elements and the source array is an array of .NET mapped types (such as System.Int32) or ABL primitive types, ABL raises a compile-time error, because (as noted previously) ABL does not automatically do the unboxing and boxing operations that are required on the elements of each array.

– If the target has an indeterminate EXTENT, the elements from the source array are copied to the target, fixing its EXTENT to the number of elements in the source array.

– If the target has a fixed EXTENT and the number of elements in the source array match the target EXTENT, the elements from the source array are copied to the target; otherwise, the assignment raises an error. This is true for both ABL and .NET source arrays.

• For a .NET and ABL array assignment where the target is a .NET array object or other object reference:

  – The source array can be any ABL array or .NET array with an element data type that is compatible with the target. If the element data type of the target array is a .NET value type, a .NET source array must be defined with elements of an identical value type. If the target array is a .NET array of mapped types, an ABL source array must be defined with elements of an ABL primitive type that implicitly maps to the target element type (see Table 23). If the target element type is not mapped (such as System.Drawing.Size), an ABL source array (like a .NET array) must be defined with elements of an identical value type. Otherwise, assignment to arrays of .NET reference type elements follow standard rules for assigning object references of related class and interface types.

  – If the target is a System.Array or a System.Object, you can assign to it any .NET source array object or any ABL source array that is defined as a supported .NET object type or as an ABL primitive type that maps implicitly to a .NET mapped data type (see Table 23). If the source is a .NET array object, ABL simply assigns it to the System.Array or System.Object reference. If the source is an ABL array, ABL creates a new .NET array object to hold the ABL array elements and assigns it to the System.Array or System.Object reference. In addition, if the ABL array elements have a primitive type, ABL automatically maps the ABL array elements into the default matching .NET object type before storing them in the specified System.Array or System.Object.

  – If the target is a .NET array of System.Object elements ("System.Object[]"), you can also assign any compatible ABL or .NET array to it. Note (as previously described) that a source array with .NET value type elements (such as System.Drawing.Size or ABL INTEGER, which resolves to the value-type, System.Int32) is not compatible. .NET requires that the element types must be identical in array assignments involving value type elements.
If the target is a `Progress.Lang.Object`, you can assign to it any .NET source array object, but not a native ABL array (which is not an object).

The EXTENT of any ABL source array and the dimensions and size of a .NET source array do not matter. As noted previously, ABL copies the elements of an ABL source array to a newly created .NET array object and stores the object into the target object reference.

**Caution:** The index for ABL arrays is 1-based, while the index for .NET arrays is generally 0-based.

- You can pass the Unknown value (?) as a parameter to a .NET method or assign the Unknown value (?) to a .NET property or data member. ABL translates the Unknown value (?) in these cases to the .NET null value. For the numeric and logical .NET primitive types listed in Table 23, when they are set to null, .NET sets a different default value—0, 0.0, or no—depending on the data type. In these cases, ABL also returns the .NET null value as the ABL Unknown value (?).

- ABL does not do any mapping between `System.Data.DataSet` or `System.Data.DataTable` method parameters, properties, or data members on one hand and ABL ProDataSets and temp-tables on the other. ABL supports data binding between ProDataSets or temp-tables (among other data sources) and .NET form controls using the `Progress.Data.BindingSource` class (the ProBindingSource). For more information, see the `Progress.Data.BindingSource` class reference entry. However, you can always directly access .NET `DataSet` and `DataTable` objects as any other .NET object, using their class members.

---

**DATASERVERS function**

Returns a list of database types your OpenEdge product supports from where it is executed. The DATASERVERS function takes no arguments.

**Syntax**

```
DATASERVERS
```

The DATASERVERS function returns a character string containing a comma-separated list of database types. For example:

```
"PROGRESS,ODBC,ORACLE"
```

You can use the returned string with the LOOKUP function to determine whether a particular type of database is supported.

**Example**

The following example displays a selection list of all supported database types:

```
DATASERVERS
```

You can use the returned string with the LOOKUP function to determine whether a particular type of database is supported.
DATA-SOURCE-MODIFIED function

Returns TRUE if data in the data source associated with the specified ProDataSet temp-table buffer has been modified.

Syntax

```plaintext
DATA-SOURCE-MODIFIED( buffer-name )
```

*buffer-name*

The name of a ProDataSet temp-table buffer.

Notes

- The AVM sets the value of this function from the SAVE-ROW-CHANGES( ) method.
- The DATA-SOURCE-MODIFIED function corresponds to the DATA-SOURCE-MODIFIED attribute.
- You can invoke the DATA-SOURCE-MODIFIED function from within a WHERE clause (unlike the corresponding attribute).

DATE function

Converts a single character string, a set of month, day, and year values, an integer expression, a DATETIME expression, or a DATETIME-TZ expression into a DATE value.

If the DATE function cannot produce a valid date given the specified argument(s), it returns a run-time error.

Syntax

```plaintext
DATE ( month , day , year )

DATE ( string )
```
DATE function

\[
\text{DATE ( \text{integer-expression} )}
\]

\[
\text{DATE ( \text{datetime-expression} )}
\]

month

A constant, field name, variable name, or expression whose value is an integer from 1 to 12, inclusive.

day

An expression whose value is an integer from 1 to the highest valid day of the month.

year

An expression whose value is the year (for example, 1994).

string

A character string containing a date value to convert into a DATE data type. The string value must have the format specified by the Date Format (-d) startup parameter (the default is mdy). Note that -d sets the display format, not the date storage format, which is fixed. Furthermore, date constants entered in procedures, or as initial values in the Data Dictionary, are always specified in month/day/year format.

You do not have to specify separator characters for the month, day, and year components of the date string; however, slashes(/), periods(.), and hyphens(-) are accepted as separator characters.

integer-expression

An expression that evaluates to a signed integer value that represents the number of days since the origin of the ABL date data type. Usually this integer is obtained from a previous operation where the date was converted to an integer using the INTEGER(ABL-date) or INT64(ABL-date) function.

The value of the expression cannot exceed the maximum date value, which is 12/31/32767.

Note: The resulting date from the DATE(integer-expression) function is guaranteed to be a valid ABL date only if the integer-expression originated from the INTEGER(ABL-date) or INT64(ABL-date) function.

datetime-expression

An expression that evaluates to a DATETIME or DATETIME-TZ. The DATE function returns the date portion of the datetime-expression as a DATE.

If datetime-expression is a DATETIME-TZ, the DATE function returns the date relative to the time zone of the DATETIME-TZ value. For example, a DATETIME-TZ field, fdt, is created in London (time zone UTC+00:00) with a value of May 5, 2002 at 7:15:03.002 am. DATE (fdt) returns 05/05/2002, regardless of the session’s time zone.
Examples

This procedure reads data from an input file that contains date information from another system stored as character strings without slashes or dashes between month, day, and year. It tries to convert these dates to ABL dates. Some formats cannot be successfully converted. For example:

**r-date.p**

/* r-date.p */
DEFINE VARIABLE cnum AS CHARACTER NO-UNDO FORMAT "x(3)".
DEFINE VARIABLE cdate AS CHARACTER NO-UNDO FORMAT "x(16)".
DEFINE VARIABLE iday AS INTEGER NO-UNDO.
DEFINE VARIABLE imon AS INTEGER NO-UNDO.
DEFINE VARIABLE iyr AS INTEGER NO-UNDO.
DEFINE VARIABLE ddate AS DATE NO-UNDO.

INPUT FROM VALUE(SEARCH("r-date.dat"))
REPEAT:
  SET cnum cdate.
  ASSIGN
    imon = INTEGER(SUBSTR(cdate,1,2))
    iday = INTEGER(SUBSTR(cdate,4,2))
    iyr = INTEGER(SUBSTR(cdate,7,2))
  /* Works for years within 50 of 2000 */
  iyr = iyr + (IF (iyr < 50) THEN 2000 ELSE 1900)
  ddate = DATE(imon,iday,iyr).

  DISPLAY ddate.
END.
INPUT CLOSE.

The following example shows the DATE (string) syntax:

**r-date2.p**

/* r-date2.p */
DEFINE VARIABLE cnum AS CHARACTER NO-UNDO FORMAT "x(3)".
DEFINE VARIABLE cdate AS CHARACTER NO-UNDO FORMAT "x(16)".
DEFINE VARIABLE idate AS DATE NO-UNDO FORMAT "99/99/9999".

INPUT FROM VALUE(SEARCH("r-date.dat"))
REPEAT:
  SET cnum cdate.
  ddate = DATE(cdate).
  DISPLAY ddate.
END.
INPUT CLOSE.

This example produces the following output. It produces no date for the first example since spaces are not a valid date separator:
**DATETIME function**

Converts date and time values, or a character string, into a DATETIME value.

**Note:** If any argument is the Unknown value (?), the result is the Unknown value (?).

**Syntax**

```
DATETIME (date-exp [, mtime-exp ])
```

```
DATETIME (string)
```

```
DATETIME (month, day, year, hours, minutes [, seconds [, milliseconds ] ])
```

date-exp

An expression whose value is a DATE.

mtime-exp

An expression whose value is an integer representing the number of milliseconds since midnight.

string

A character expression whose value is a string containing a DATETIME. The date portion of the string must have the format specified by the DATE-FORMAT attribute. The time portion must be in a valid time format (HH:MM:SS, and so on).

month

An expression whose value is an integer from 1 to 12, inclusive.

day

An expression whose value is an integer from 1 to the highest valid day of the month.

---

**DATETIME function**

Converts date and time values, or a character string, into a DATETIME value.

**Note:** If any argument is the Unknown value (?), the result is the Unknown value (?).

**Syntax**

```
DATETIME (date-exp [, mtime-exp ])
```

```
DATETIME (string)
```

```
DATETIME (month, day, year, hours, minutes [, seconds [, milliseconds ] ])
```

date-exp

An expression whose value is a DATE.

mtime-exp

An expression whose value is an integer representing the number of milliseconds since midnight.

string

A character expression whose value is a string containing a DATETIME. The date portion of the string must have the format specified by the DATE-FORMAT attribute. The time portion must be in a valid time format (HH:MM:SS, and so on).

month

An expression whose value is an integer from 1 to 12, inclusive.

day

An expression whose value is an integer from 1 to the highest valid day of the month.
year
An expression that evaluates to a year.

hours
An expression whose value is an integer from 0 to 23, inclusive.

minutes
An expression whose value is an integer from 0 to 59, inclusive.

seconds
An expression whose value is an integer from 0 to 61, inclusive. The upper limit is 61 for leap seconds.

milliseconds
An expression whose value is an integer from 0 to 999, inclusive.

Example
Following is an example of using the DATETIME function:

```sql
DEFINE VARIABLE my-datetime AS DATETIME NO-UNDO.
/* This statement is equivalent to "my-datetime = NOW". */
my-datetime = DATETIME(TODAY, MTIME).
```

The following statements result in the same DATETIME value:

```sql
my-datetime = DATETIME(5, 5, 2002, 7, 15, 3).
my-datetime = DATETIME("05-05-2002 07:15:03").
```

See also
ADD-INTERVAL function, DATE function, DATE-FORMAT attribute, DATETIME-TZ function, DAY function, ETIME function, INTERVAL function, ISO-DATE function, MONTH function, MTIME function, NOW function, TIME function, TIMEZONE function, TODAY function, WEEKDAY function, YEAR function, YEAR-OFFSET attribute

---

**DATETIME-TZ function**

Converts a date, time, and time zone value, or a character string, into a DATETIME-TZ value.

**Note:** If any argument is the Unknown value (?), the result is the Unknown value (?).

**Syntax**

```sql
DATETIME-TZ (date-exp [, mtime-exp [, timezone-exp ] ] )
```

```sql
DATETIME-TZ (datetime-exp [, timezone-exp ] )
```
DATETIME-TZ function

DATETIME-TZ (datetime-tz-exp [, timezone-exp ])

DATETIME-TZ (month, day, year, hours, minutes [, seconds [, milliseconds [, timezone-exp ] ] ])

DATETIME-TZ (string)

date-exp

An expression whose value is a DATE.

mtime-exp

An expression whose value is an integer representing the number of milliseconds since midnight.

timezone-exp

An expression whose value is an integer representing the time zone offset from Coordinated Universal Time (UTC) in minutes. If not specified, the function uses the session’s time zone.

datetime-exp

An expression whose value is a DATETIME.

datetime-tz-exp

An expression whose value is a DATETIME-TZ. Use this option to convert a DATETIME-TZ from one time zone to another.

month

An expression whose value is an integer from 1 to 12, inclusive.

day

An expression whose value is an integer from 1 to the highest valid day of the month.

year

An expression that evaluates to a year.

hours

An expression whose value is an integer from 0 to 23, inclusive.

minutes

An expression whose value is an integer from 0 to 59, inclusive.
**seconds**

An expression whose value is an integer from 0 to 61, inclusive. The upper limit is 61 for leap seconds.

**milliseconds**

An expression whose value is an integer from 0 to 999, inclusive.

**string**

A character expression whose value is a string containing a DATETIME-TZ. The date portion of the string must have the format specified by the DATE-FORMAT attribute. The time portion must be in a valid time format (HH:MM:SS, and so on). If the string contains a time zone, it must be in +HH:MM format. If the string does not contain a time zone, the DATETIME-TZ inherits the session’s time zone.

**Example**

Following is an example of using the DATETIME-TZ function:

```sql
DEFINE VARIABLE my-datetime-tz AS DATETIME-TZ NO-UNDO.
/* This statement is equivalent to "my-datetime-tz = NOW". */
my-datetime-tz = DATETIME-TZ(TODAY, MTIME, TIMEZONE).
```

The following statements result in the same DATETIME-TZ value (when SESSION:DATE-FORMAT is mdy):

```sql
my-datetime-tz = DATETIME-TZ(5, 5, 2002, 7, 15, 3, 0, -300).
my-datetime-tz = DATETIME-TZ("05-05-2002 07:15:03-05:00").
```

**See also**

ADD-INTERVAL function, DATE function, DATE-FORMAT attribute, DATETIME function, DAY function, ETIME function, INTERVAL function, ISO-DATE function, MONTH function, MTIME function, NOW function, TIME function, TIMEZONE function, TODAY function, WEEKDAY function, YEAR function, YEAR-OFFSET attribute

---

**DAY function**

Evaluates a date expression and returns a day of the month as an INTEGER value from 1 to 31, inclusive.

**Syntax**

```sql
DAY ( date )
```

```sql
DAY ( datetime-expression )
```

date

An expression whose value is a DATE.
datetime-expression

An expression that evaluates to a DATETIME or DATETIME-TZ. The DAY function returns the day of the month of the date part of the DATETIME or DATETIME-TZ value.

Example

This procedure determines the date one year from a given date, allowing for leap years. You could simply determine a date 365 days later by adding 365 to the d1 variable, but that might not produce the correct result (for example, 1/1/92 + 365 days is 12/31/92).

r-day.p

```abl
DEFINE VARIABLE d1 AS DATE NO-UNDO LABEL "Date".
DEFINE VARIABLE d2 AS DATE NO-UNDO LABEL "Same date next year".
DEFINE VARIABLE d-day AS INTEGER NO-UNDO.
DEFINE VARIABLE d-mon AS INTEGER NO-UNDO.

REPEAT:
    SET d1.
    d-day = DAY(d1).
    d-mon = MONTH(d1).
    IF d-mon = 2 AND d-day = 29 THEN d-day = 28.
    d2 = DATE(d-mon, d-day, YEAR(d1) + 1).
    DISPLAY d2.
END.
```

See also

ADD-INTERVAL function, DATE function, DATE-FORMAT attribute, DATETIME function, DATETIME-TZ function, ETIME function, INTERVAL function, ISO-DATE function, MONTH function, MTIME function, NOW function, TIME function, TIMEZONE function, TODAY function, WEEKDAY function, YEAR function, YEAR-OFFSET attribute

DBCODEPAGE function

Returns, as a character string, the name of a connected database’s code page.

Syntax

```
DBCODEPAGE ( { integer-expression | logical-name | alias } )
```

integer-expression

The sequence number of a database the ABL session is connected to. For example, DBCODEPAGE(1) returns information on the first database the ABL session is connected to, DCODEPAGE(2) returns information on the second database the ABL session is connected to, etc. If you specify a sequence number that does not correspond to a database the ABL session is connected to, the DBCODEPAGE function returns the Unknown value (?).

logical-name

A character expression that specifies the database by its logical name or alias.

A code page maps each character in a character set to a numeric value. For an OpenEdge database, DBCODEPAGE returns the code page of the database represented by the integer expression, logical name, or alias. For a non-OpenEdge database, DBCODEPAGE returns the value originally inserted when the schema was created.
There are three possible types of non-OpenEdge code pages:

- Physical data source for the database
- Code page of a non-OpenEdge vendor library linked in with an OpenEdge dataserver executable (either dynamically or at compile time)
- Code page that is in the schema holder that is part of the create activity

If any parameter is invalid, it returns the Unknown value (`?`).

Example

This procedure displays the logical name and code page of all connected databases:

```
r-dbcp.p

DEFINE VARIABLE ix AS INTEGER NO-UNDO.

REPEAT ix = 1 TO NUM-DBS:
    DISPLAY LDBNAME(ix) DBCODEPAGE(ix) FORMAT "x(19).
END.
```

Note

A database must be connected in order for the DBCODEPAGE function to work as described.

See also

ALIAS function, CONNECT statement, CONNECTED function, CREATE ALIAS statement, CREATE CALL statement, DATASERVERS function, DBCOLLATION function, DBRESTRICTIONS function, DBTYPE function, DBVERSION function, DELETE ALIAS statement, DISCONNECT statement, FRAME-DB function, LDBNAME function, PDBNAME function, SDBNAME function

**DBCOLLATION function**

Returns, as a character string, the name of the collating sequence for character set information contained in the database. This name corresponds to the definition of the collating sequence contained in the `convmap.dat` file, which usually resides in the $DLC directory. If any parameter is invalid, DBCOLLATION returns the Unknown value (`?`).

**Syntax**

```
DBCOLLATION
   ( { integer-expression | logical-name | alias } )
```

**integer-expression**

The sequence number of a database the ABL session is connected to. For example, DBCOLLATION(1) returns information on the first database the ABL session is connected to, DBCOLLATION(2) returns information on the second database the ABL session is connected to, etc. If you specify a sequence number that does not correspond to a database the ABL session is connected to, the DBCOLLATION function returns the Unknown value (`?`).

**logical-name or alias**

A character expression that specifies the database by its logical name or alias.
DBNAME function

This procedure displays the logical name and collation of all connected databases:

r-dbcoll.p

```fortran
DEFINE VARIABLE ix AS INTEGER NO-UNDO  
REPEAT ix = 1 TO NUM-DBS:  
    DISPLAY LDBNAME(ix) DBCOLLATION(ix) FORMAT "x(19)".  
END.
```

Notes

- OpenEdge and non-OpenEdge dataservers can evaluate the syntactical expression stated in a DBCOLLATION function. However, the methods used to process multiple byte code pages can differ based on the actual server used. Keep this point in mind if the actual results you receive differ from the results you expected.
- A database must be connected in order for the DBCOLLATION function to work as described.

See also

ALIAS function, CONNECT statement, CONNECTED function, CREATE ALIAS statement, CREATE CALL statement, DATASERVERS function, DBCODEPAGE function, DBRESTRICTIONS function, DBVERSION function, DELETE ALIAS statement, DISCONNECT statement, FRAME-DB function, LDBNAME function, NUM-DBS function, PDBNAME function, SDBNAME function

DBNAME function

Returns, as a character string, the name of the logical database currently in use or the name of your first connected database.

Syntax

```
DBNAME
```

Example

This portion of a procedure defines a header frame to hold a date, page number, database name, and user ID:

r-dbname.p

```fortran
DEFINE VARIABLE pageno AS INTEGER NO-UNDO FORMAT "zzz9" INITIAL 1.  
FORM HEADER "Date:" TO 10 TODAY  
    "Page:" AT 65 pageno SKIP  
    "Database:" TO 10 DBNAME FORMAT "x(60)" SKIP  
    "Userid:" TO 10 USERID WITH NO-BOX NO-LABELS.  
VIEW.
```

Notes

- The AVM returns the database name in the same form you used when you connected to the database. If you used a fully qualified pathname, the AVM returns the full directory pathname (such as /usr/acctg/gl on UNIX or C:\acctg\gl in Windows). If you used a name relative to your current working directory, then the AVM returns that name (for example, gl).
- Unless you define a format, the database name is displayed in a character field with the default format of x(8).
• A database must be connected in order for the DBNAME function to work as described.

See also
ALIAS function, CONNECT statement, CONNECTED function, CREATE ALIAS statement, CREATE CALL statement, DATASERVERS function, DBVERSION function, DELETE ALIAS statement, DISCONNECT statement, FRAME-DB function, LDBNAME function, NUM-DBS function, PDBNAME function, SDBNAME function

DBPARAM function

Returns, as a character string, a comma-separated list of the parameters used to connect to the database.

Syntax

```plaintext
DBPARAM ( integer-expression | logical-name | alias )
```

integer-expression

The sequence number of a database the ABL session is connected to. For example, DBPARAM(1) returns information on the first database the ABL session is connected to, DBPARAM(2) returns information on the second database the ABL session is connected to, etc. If you specify a sequence number that does not correspond to a database the ABL session is connected to, the DBPARAM function returns the Unknown value (?)..

logical-name or alias

These forms of the DBPARAM function require a character expression as a parameter. An unquoted character string is not permitted. If the parameter is an alias or the logical name of a connected database, then the AVM returns the comma-separated parameter list. Otherwise, it returns the Unknown value (?).

Notes

• A database must be connected for the DBPARAM function to work as described.

• If the CONNECT statement does not contain a -db (database) parameter, which is permissible, the string DBPARAM returns includes the -db parameter and the database name.

• If the CONNECT statement contains the -pf parameter, which refers to a parameter file, the string DBPARAM returns includes the parameters in the file without “-pf” or any reference to the file.

• If the CONNECT statement contains a userid and a password, the string DBPARAM returns includes only the userid.

• The database can connect through the CONNECT statement, the command line, or an auto-connection.

See also
DBCODEPAGE function, DBCOLLATION function, DBTYPE function, DBVERSION function
**DB-REMOTE-HOST function**

Returns a character string containing the IP address of the database connection. The IP address format is determined by the Internet Protocol used when the connection was established. A single input parameter identifies the database, which can be either the logical database name or database number. If the database is not connected using TCP/IP or the \(-ipver\) IPv6 startup parameter is not used, the function returns the Unknown value (?).

**Syntax**

```
DB-REMOTE-HOST ( { logical-name | integer-expression } )
```

*logical-name*

A character expression specifying the logical name of a connected database.

*integer-expression*

The sequence number of a connected database. For example, `DB-REMOTE-HOST(1)` returns information on the first connected database, `DB-REMOTE-HOST(2)` returns information on the second connected database, and so on.

**Note**

For more information on the Internet Protocol (IP) version (`-ipver`) startup parameter, see *OpenEdge Deployment: Startup Command and Parameter Reference*.

**See also**

REMOTE-HOST attribute

---

**DBRESTRICTIONS function**

Returns a character string that describes features that are not supported for this database. You can use this function with OpenEdge DataServers.

**Syntax**

```
DBRESTRICTIONS ( { integer-expression | logical-name | alias } [ , table-name ] )
```

*integer-expression*

The sequence number of a database the ABL session is connected to. For example, `DBRESTRICTIONS(1)` returns information on the first database the ABL session is connected to, `DBRESTRICTIONS(2)` returns information on the second database the ABL session is connected to, and so on. If you specify a sequence number that does not correspond to a database the ABL session is connected to, the DBRESTRICTIONS function returns the Unknown value (?).

*logical-name or alias*

These forms of the DBRESTRICTIONS function require a character expression as a parameter. An unquoted character string is not permitted. If the parameter is an alias or the
logical name of a connected database, then the AVM returns the database restrictions string. Otherwise, it returns the Unknown value (?).

**table-name**

A character expression equal to the name of a table in the specified database. An unquoted character string is not permitted. If the table name is valid, DBRESTRICTIONS returns the list of unsupported features for the specified table. Otherwise, it returns the Unknown value (?).

**Example**

This procedure displays the logical name and database restrictions of all connected databases:

```
r-dbrest.p
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
REPEAT ix = 1 to NUM-DBS:
   DISPLAY LDBNAME(ix) LABEL "Database"
   DBRESTRICTIONS(ix) FORMAT "x(40)" LABEL "Restrictions".
END.
```

**Notes**

- If you want to use the DBRESTRICTIONS function for a database, you must be connected to the database in the current ABL session.

- DBRESTRICTIONS returns a string. This string is a comma-separated list of keywords that represent features not supported by the specified database. Table 25 shows the possible keywords and their descriptions.

**Table 25: DBRESTRICTIONS keyword values**

<table>
<thead>
<tr>
<th>Keyword</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>COUNT-OF</td>
<td>Cannot use the COUNT-OF function.</td>
</tr>
<tr>
<td>LAST</td>
<td>Cannot invoke the FIND LAST statement.</td>
</tr>
<tr>
<td>PREV</td>
<td>Cannot invoke the FIND PREV statement.</td>
</tr>
<tr>
<td>READ-ONLY</td>
<td>The database or table is available for read only.</td>
</tr>
<tr>
<td>RECID</td>
<td>Cannot use the RECID function.</td>
</tr>
<tr>
<td>SET-CURRENT-VALUE</td>
<td>Cannot set the current value of sequence generators.</td>
</tr>
<tr>
<td>SETUSERID</td>
<td>Cannot use the SETUSERID function.</td>
</tr>
</tbody>
</table>

For example, if the database is accessed through a manager that does not support FIND LAST and FIND PREV, then the DBRESTRICTIONS function returns the string LAST, PREV.

- The possible keyword values returned by DBRESTRICTIONS depends on the DataServer type. Table 26 shows the possible values returned for each DataServer.
DBTASKID function

Returns an INTEGER value that uniquely identifies a database’s transaction.

Syntax

```plaintext
DBTASKID ( integer-expression | logical-name | alias )
```

integer-expression

The sequence number of a database the ABL session is connected to. For example, `DBTASKID(1)` returns information on the first database the ABL session is connected to, `DBTASKID(2)` returns information on the second database the ABL session is connected to, etc. If you specify a sequence number that does not correspond to a database the ABL session is connected to, the DBTASKID function returns the Unknown value (?).

logical-name or alias

A character expression that evaluates to the logical name or alias of a database that is connected to the current ABL session. If the character expression does not evaluate to the logical name or alias of a connected database, DBTASKID returns the Unknown value (?).

Note: You must enclose all character strings in quotes.

Notes

- If the application is not in a transaction, DBTASKID returns the Unknown value (?).

Table 26: DBRESTRICTIONS return values by DataServer

<table>
<thead>
<tr>
<th>DataServer</th>
<th>Possible return values</th>
</tr>
</thead>
<tbody>
<tr>
<td>ODBC</td>
<td>&quot;COUNT-OF,LAST,PREV,READ-ONLY,RECID,SETUSERID&quot;</td>
</tr>
<tr>
<td>ORACLE</td>
<td>&quot;LAST,PREV,READ-ONLY,RECID,SETUSERID,SET-CURRENT-VALUE&quot;</td>
</tr>
<tr>
<td>OpenEdge</td>
<td>&quot;READ-ONLY&quot;</td>
</tr>
</tbody>
</table>

Note: The available DataServers depend on your version of OpenEdge. For more information, see your OpenEdge DataServer documentation.
**DBTYPE function**

Returns, as a character string, the database type of a currently connected database. This function returns one of the following strings: "MSS", "ODBC", "ORACLE", or "PROGRESS".

**Syntax**

```
DBTYPE ( integer-expression | logical-name | alias )
```

**integer-expression**

The sequence number of a database the ABL session is connected to. For example, DBTYPE(1) returns information on the first database the ABL session is connected to, DBTYPE(2) returns information on the second database the ABL session is connected to, etc. If you specify a sequence number that does not correspond to a database the ABL session is connected to, the DBTYPE function returns the Unknown value (?).

**logical-name or alias**

These forms of the DBTYPE function require a quoted character string or a character expression as a parameter. An unquoted character string is not permitted. If the parameter is an alias of a connected database or the logical name of a connected database, then the AVM returns the database type. Otherwise, it returns the Unknown value (?).

**Example**

This procedure displays the logical name and database type of all connected databases:

```
r-dbtpe.p

DEFINE VARIABLE ix AS INTEGER NO-UNDO.
REPEAT ix = 1 TO NUM-DBS:
   DISPLAY LDBNAME(ix) DBTYPE(ix) FORMAT "x(40)".
END.
```
DBVERSION function

You can reference the DBTYPE function within a preprocessor expression. For more information, see the &IF, &THEN, &ELSEIF, &ELSE, and &ENDIF preprocessor directives reference entry.

See also ALIAS function, CONNECT statement, CONNECTED function, CREATE ALIAS statement, CREATE CALL statement, DATASERVERS function, DBCODEPAGE function, DBCOLLATION function, DBRESTRUCTIONS function, DBVERSION function, DELETE ALIAS statement, DISCONNECT statement, FRAME-DB function, LDBNAME function, NUM-DBS function, PDBNAME function, SDBNAME function

DBVERSION function

Returns, as a character string, the version number of an OpenEdge database.

Syntax

\[
\text{DBVERSION ( integer-expression | logical-name | alias )}
\]

integer-expression

The sequence number of a database the ABL session is connected to. For example, DBVERSION(1) returns information on the first database the ABL session is connected to, DBVERSION(2) returns information on the second database the ABL session is connected to, etc. If you specify a sequence number that does not correspond to a database the ABL session is connected to, the DBVERSION function returns the Unknown value (?).

logical-name or alias

These forms of the DBVERSION function require a quoted character string or a character expression as a parameter. If the parameter is an alias of a connected database or the logical name of a connected database, then the AVM returns the version number. Otherwise, it returns the Unknown value (?).

Example

This procedure displays the version number of all connected databases:

\[
\text{r-dbvers.p}
\]

DEFINE VARIABLE ix AS INTEGER NO-UNDO.

REPEAT ix = 1 TO NUM-DBS:
  DISPLAY LDBNAME(ix) DBVERSION(ix) WITH 1 DOWN.
END.

Note

DBVERSION does not apply to non-OpenEdge data sources.

See also ALIAS function, CONNECT statement, CONNECTED function, CREATE ALIAS statement, CREATE CALL statement, DATASERVERS function, DBCODEPAGE function, DBCOLLATION function, DBRESTRUCTIONS function, DBTYPE function, DELETE ALIAS statement, DISCONNECT statement, FRAME-DB function, LDBNAME function, NUM-DBS function, PDBNAME function, SDBNAME function
DDE ADVISE statement
(Windows only)

Instructs the dynamic data exchange (DDE) server associated with a conversation to either create or remove an advise link to the specified data item.

This statement is supported only for backward compatibility. Use the Component Object Model (COM) instead.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
DDE ADVISE ddeid { START | STOP } ITEM name
    [ TIME seconds ]
    [ NO-ERROR ]
```

**ddeid**

An integer expression equal to the channel number of the conversation opened for the specified data item. It is the value returned by the DDE INITIATE statement that opened the conversation.

**START**

Instructs the server to create a link to a data item, and notify the ABL client when the specified data item changes value.

**STOP**

Instructs the server to remove the link to the specified data item, and stop monitoring its value.

**ITEM name**

Specifies the name of the server data item to which the link is created or removed. The data item name is a character expression that identifies the data item according to the conventions of the server application (for example, the row and column coordinates of a worksheet cell, such as R2C1 in Microsoft Excel). After creating a link, when the value of the data item specified by name changes, the AVM triggers a DDE-NOTIFY event for the frame that owns the conversation, allowing the client to retrieve the new value.

**TIME seconds**

Specifies the maximum number of seconds that the ABL client waits for the DDE ADVISE statement to complete, where seconds is an integer expression. If you do not specify the TIME option or specify a value of 0, the AVM waits indefinitely for the statement to complete.

**NO-ERROR**

By default, if the statement fails to create or remove the link, the AVM raises the ERROR condition, and posts the error to the DDE frame DDE-ERROR attribute. If you specify
NO-ERROR, the AVM does not raise the ERROR condition, but does post the error to the DDE frame.

**Example**

The following fragment shows how to use the DDE ADVISE to set up a procedure to capture a rate-of-change value as it changes in a dynamic model run in a Microsoft Excel worksheet. The example assumes that the Microsoft Excel application is running, and has opened the default Excel worksheet, Sheet1, which runs the model.

After the conversation is opened, the DDE ADVISE statement links to the worksheet cell that maintains the latest rate-of-change value (second column of the fourth row, or R4C2). Every time this cell changes value, the AVM posts a DDE-NOTIFY event to the frame DDEframe, where the value is retrieved using the DDE GET statement, and stored as a decimal in the ChangeRate variable. Meanwhile, if the REPEAT block detects a ChangeRate value greater than 7.5%, the link to cell R4C2 is closed and the procedure continues.

```abl
DEFINE VARIABLE Sheet1 AS INTEGER. NO-UNDO. /* DDE-ID to worksheet */
DEFINE VARIABLE ChangeRate AS DECIMAL NO-UNDO  /* Rate of change... */
    INITIAL 0.0. /* ...starting at zero */
DEFINE VARIABLE CellData AS CHARACTER NO-UNDO. /* Worksheet cell output */
DEFINE VARIABLE DDEframe AS HANDLE NO-UNDO. /* DDE frame handle */

CREATE FRAME DDEframe
TRIGGERS: /* DDE frame and code to receive */
    ON DDE-NOTIFY DO: /* Rate of change data from Excel */
        DDE GET Sheet1 TARGET CellData ITEM "R4C2".
        ChangeRate = DECIMAL(CellData).
    END.
END TRIGGERS.

/* Open conversation with "Sheet1" and link to rate-of-change value. */
DDE INITIATE Sheet1 FRAME DDEframe APPLICATION "Excel" TOPIC "Sheet1".
DDE ADVISE Sheet1 START ITEM "R4C2".

/* Do some processing while the rate-of-change is within 7.5% */
REPEAT WHILE ChangeRate <= 7.5:
    . . .
END. /* 7.5% processing */

/* Go on to other things once the rate of change goes above 7.5%. */
DDE ADVISE Sheet1 STOP ITEM "R4C2".
    . . .
```

**Notes**

- After a DDE-NOTIFY event is triggered for the conversation, the client application must use the DDE GET statement in a trigger block for the event to retrieve the latest value for name.

- For more information on using the DDE protocol to exchange data with non-ABL applications, see *OpenEdge Development: Programming Interfaces*.

**See also**

DDE GET statement, DDE INITIATE statement

---

**DDE EXECUTE statement**

*(Windows only)*

Instructs a dynamic data exchange (DDE) server application to execute one or more application commands.
This statement is supported only for backward compatibility. Use the Component Object Model (COM) instead.

**Note:** Does not apply to SpeedScript programming.

### Syntax

```
DDE EXECUTE ddeid COMMAND string
  [ TIME seconds ]
  [ NO-ERROR ]
```

**ddeid**

An integer expression equal to the channel number of a conversation opened to execute the specified command string. It is the value returned by the DDE INITIATE statement that opened the conversation. You can usually execute commands using a conversation opened for the System topic of the server application.

**COMMAND string**

Specifies the command or commands for the server to execute, where `string` is a character expression containing commands that are defined by the server application (for example, the `[select(...)` command in Microsoft Excel).

**TIME seconds**

Specifies the maximum number of seconds that the ABL client waits for the DDE EXECUTE statement to complete, where `seconds` is an integer expression. If you do not specify the TIME option or specify a value of 0, the AVM waits indefinitely for the statement to complete.

**NO-ERROR**

By default, if the statement fails to execute the command(s), the AVM raises the ERROR condition and posts the error to the DDE frame DDE-ERROR attribute. If you specify NO-ERROR, the AVM does not raise the ERROR condition but does post the error to the DDE frame.

### Example

The following fragment shows how to use the DDE EXECUTE statement. The procedure executes Microsoft Excel internally and opens a conversation for the Excel System topic. The System topic lets you execute Excel functions. This example uses the DDE EXECUTE statement to create a new Excel worksheet using the Excel new function:
DDE GET statement

(D windows only)

Retrieves the value of a dynamic data exchange (DDE) server data item that has changed and triggered a DDE-NOTIFY event.

This statement is supported only for backward compatibility. Use the Component Object Model (COM) instead.

**Note:** Does not apply to SpeedScript programming.

### Syntax

```
DDE GET ddeid TARGET field ITEM name
  [ TIME seconds ]
  [ NO-ERROR ]
```

**ddeid**

An integer expression that specifies the channel number of the conversation that triggered the DDE-NOTIFY event. You can obtain the value of **ddeid** from the DDE-ID attribute of the frame to which the DDE-NOTIFY event was posted.

**TARGET field**

Specifies a character field or variable that receives the value of the server data item as a character string.

### Notes

- For more information on commands available in your server application, see the documentation for that application.
- For more information on using the DDE protocol to exchange data with non-ABL applications, see *OpenEdge Development: Programming Interfaces*.

### See also

DDE INITIATE statement
ITEM name

Specifies the server data item that changed and triggered the DDE-NOTIFY event, where name is a character expression that identifies the name of the data item in the server application. You can obtain the value of name from the DDE-ITEM attribute of the frame to which the DDE-NOTIFY event was posted.

TIME seconds

Specifies the maximum number of seconds that the ABL client waits for the DDE GET statement to complete where seconds is an integer expression. If you do not specify the TIME option or specify a value of 0, the AVM waits indefinitely for the statement to complete.

NO-ERROR

By default, if the statement fails to retrieve the data item value, the AVM raises the ERROR condition, and posts the error to the DDE frame DDE-ERROR attribute. If you specify NO-ERROR, the AVM does not raise the ERROR condition but does post the error to the DDE frame.

Example

The following fragment shows how to use the DDE GET statement to set up a procedure to capture a rate-of-change value as it changes in a dynamic model run in a Microsoft Excel worksheet. The example assumes that the Microsoft Excel application is running, and has opened the default Excel worksheet, Sheet1, which runs the model.

After the conversation is opened, the DDE ADVISE statement links to the worksheet cell that maintains the latest rate-of-change value (2nd column of the 4th row, or R4C2). Every time this cell changes value, the AVM posts a DDE-NOTIFY event to the frame DDEframe, where the value is retrieved using the DDE GET statement, and stored as a decimal in the ChangeRate variable. Meanwhile, if the REPEAT block detects a ChangeRate value greater than 7.5%, the the link to cell R4C2 is closed and the procedure continues.

```abl
DEFINE VARIABLE Sheet1 AS INTEGER NO-UNDO. /* DDE-ID to worksheet */
DEFINE VARIABLE ChangeRate AS DECIMAL NO-UNDO /* Rate of change... */
INITIAL 0.0. /* ...starting at 0 */
DEFINE VARIABLE CellData AS CHARACTER NO-UNDO. /* Worksheet cell output */
DEFINE VARIABLE DDEframe AS HANDLE NO-UNDO. /* DDE frame handle */
CREATE FRAME DDEframe
TRIGGERS: /* DDE frame and code to receive */
  ON DDE-NOTIFY DO: /* Rate of change data from Excel */
    DDE GET Sheet1 TARGET CellData ITEM "R4C2".
    ChangeRate = DECIMAL(CellData).
  END.
END TRIGGERS.

/* Open conversation with Sheet1 and link to rate-of-change value. */
DDE INITIATE Sheet1 FRAME DDEframe APPLICATION "Excel" TOPIC "Sheet1".
DDE ADVISE Sheet1 START ITEM "R4C2".

/* Do some processing while the rate-of-change is within 7.5% */
REPEAT WHILE ChangeRate <= 7.5:
  . . .
END. /* 7.5% processing */

/* Go on to other things once the rate of change goes above 7.5%. */
DDE ADVISE Sheet1 STOP ITEM "R4C2".
. . .
```
**Notes**

- The AVM posts each DDE-NOTIFY event to the frame that owns the conversation opened for the linked data item.
- You can invoke this function in the trigger block for each frame that owns a conversation containing advise links. Only frames that own conversations linked to data items with the DDE-ADVISE statement can receive DDE-NOTIFY events.
- For more information on using the DDE protocol to exchange data with non-ABL applications, see *OpenEdge Development: Programming Interfaces*.

**See also** DDE ADVISE statement, DDE INITIATE statement

---

**DDE INITIATE statement**

**(Windows only)**

Opens a dynamic data exchange (DDE) client conversation for a specified DDE server application and topic, and associates the new conversation with an ABL frame. To identify the conversation, the statement returns an integer as a unique channel number for this conversation.

This statement is supported only for backward compatibility. Use the Component Object Model (COM) instead.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```plaintext
DDE INITIATE ddeid-var
APPLICATION server-name TOPIC topic-name [NO-ERROR]

FRAME frame-handle
```

- `ddeid-var`: An integer variable or field that receives the channel number for the newly opened DDE conversation.
- `FRAME frame-handle`: Specifies the handle of the frame that owns the conversation, where `frame-handle` is a HANDLE expression. A frame can own more than one conversation. The AVM records the status of the most recent conversation exchange in a set of DDE frame attributes. These attributes record the status of every dynamic data exchange, including advise exchanges (exchanges triggered by DDE-NOTIFY events). The DDE frame attributes include:
  - **DDE-ERROR** — The DDE error code returned by the most recent exchange
  - **DDE-ID** — The channel number of the conversation that had the most recent exchange
  - **DDE-ITEM** — The name of the data item referenced by the most recent exchange
  - **DDE-NAME** — The name of the server application in the most recent exchange
  - **DDE-TOPIC** — The name of the topic of the most recent exchange
APPLICATION server-name

Specifies the name of the server application for the conversation, where server-name is a character expression. The value of server-name must be unique for each DDE server on your system. It is usually the filename of the server executable without the extension (for example, the name EXCEL in Microsoft Excel).

TOPIC topic-name

Specifies the name of the topic of the conversation, where topic-name is a character expression. The value of topic-name identifies a category defined by the server application. This is usually the name of a file or other container that includes one or more data items (for example, the name of a worksheet, such as Sheet1 in Microsoft Excel). An ABL client can only exchange data with server data items included in the topic of an open conversation.

NO-ERROR

By default, if the statement fails to open a conversation, the AVM raises the ERROR condition and posts the error to the DDE frame DDE-ERROR attribute. If you specify NO-ERROR, the AVM does not raise the ERROR condition but does post the error to the DDE frame.

Example

The following fragment shows a typical use of the DDE INITIATE statement. It assumes that the Microsoft Excel application is running, and has created the default Excel worksheet, Sheet1. It then uses the DDE INITIATE statement to open a conversation with Sheet1 as the topic. This allows the AVM to exchange data with the cells of the worksheet. In this example, the fragment assigns column headings to the top row of the first three columns in the worksheet:

```
DEFINE VARIABLE Sheet1 AS INTEGER NO-UNDO. /* DDE-ID to worksheet topic */
DEFINE VARIABLE DDEframe AS HANDLE NO-UNDO. /* DDE frame handle */

/* Create DDE frame */
CREATE FRAME DDEframe
  ASSIGN visible = TRUE
  hidden = TRUE.

/* Open a DDE conversation with Sheet1 and assign column headings. */
DDE INITIATE Sheet1 FRAME DDEframe APPLICATION "Excel" TOPIC "Sheet1".
DDE SEND Sheet1 SOURCE "Name" ITEM "R1C1".
DDE SEND Sheet1 SOURCE "YTD Sales" ITEM "R1C2".
DDE SEND Sheet1 SOURCE "State" ITEM "R1C3".

```

Notes

- The specified DDE server application must be running on the Windows desktop before you can invoke the DDE INITIATE statement.
- You can close a DDE conversation in three ways: use the DDE TERMINATE statement, leave the scope of the frame that owns the conversation, or terminate the server application or topic associated with the application.
- For more information on using the DDE protocol (including DDE frame attributes) to exchange data with non-ABL applications, see OpenEdge Development: Programming Interfaces.

See also

DDE TERMINATE statement
DDE REQUEST statement
(Windows only)

Retrieves the current value of a dynamic data exchange (DDE) server data item associated with the specified DDE conversation.

This statement is supported only for backward compatibility. Use the Component Object Model (COM) instead.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
DDE REQUEST ddeid TARGET field ITEM name
   [ TIME seconds ]
   [ NO-ERROR ]
```

**ddeid**

An integer expression that equals the channel number of the conversation opened for the specified data item. It is the value returned by the DDE INITIATE statement that opened the conversation.

**TARGET field**

Specifies a character field or variable that receives the value of the data item as a character string.

**ITEM name**

Specifies the name of the server data item from which to retrieve a value. The data item name is a character expression that identifies the data item according to the conventions of the server application (for example, the row and column coordinates of a worksheet cell, such as R2C1 in Microsoft Excel).

**TIME seconds**

Specifies the maximum number of seconds that the ABL client waits for the DDE REQUEST statement to complete, where seconds is an integer expression. If you do not specify the TIME option or specify a value of 0, the AVM waits indefinitely for the statement to complete.

**NO-ERROR**

By default, if the statement fails to retrieve the data item value, the AVM raises the ERROR condition and posts the error to the DDE frame DDE-ERROR attribute. If you specify NO-ERROR, the AVM does not raise the ERROR condition but does post the error to the DDE frame.

**Example**

The following fragment shows a typical use of the DDE REQUEST statement. It assumes that the Microsoft Excel application is running, and has created the default Excel worksheet, Sheet1. It then uses the DDE INITIATE statement to open a conversation with Sheet1 as the topic. This allows the AVM to exchange data with the cells of the worksheet.
In this example, the fragment builds 10 new Customer records from data obtained from the first 4 columns in the worksheet using the DDE REQUEST statement. The data includes Customer name, year-to-date sales, state, and zip code. (The requests start from row 2, because row 1 contains column headings.)

```
DEFINE VARIABLE Rowi AS INTEGER NO-UNDO. /* Worksheet row counter */
DEFINE VARIABLE ItemName AS CHARACTER NO-UNDO. /* Item Name */
DEFINE VARIABLE CustName AS CHARACTER NO-UNDO. /* Customer name receptor */
DEFINE VARIABLE YTDsales AS CHARACTER NO-UNDO. /* YTD sales receptor */
DEFINE VARIABLE StateAbr AS CHARACTER NO-UNDO. /* State name receptor */
DEFINE VARIABLE ZipCode AS CHARACTER NO-UNDO. /* Zip code receptor */
DEFINE VARIABLE Sheet1 AS INTEGER NO-UNDO. /* DDE-ID to worksheet */
DEFINE VARIABLE DDEframe AS HANDLE NO-UNDO. /* DDE frame handle */

CREATE FRAME DDEframe. /* Create DDE frame */

/* Open a DDE conversation with Sheet1 and create 10 Customer records from the data in four columns of the worksheet. */
DDE INITIATE Sheet1 FRAME DDEframe APPLICATION "Excel" TOPIC "Sheet1".

REPEAT Rowi = 2 TO 11:
    CREATE Customer.
    Customer.CustNum = Rowi - 1.
    ItemName = "R" + STRING(Rowi) + "C1".
    DDE REQUEST Sheet1 TARGET CustName ITEM ItemName.
    Customer.Name = CustName.
    ItemName = "R" + STRING(Rowi) + "C2".
    DDE REQUEST Sheet1 TARGET YTDsales ITEM ItemName.
    Customer.YtdSls = DECIMAL(YTDsales).
    ItemName = "R" + STRING(Rowi) + "C3".
    DDE REQUEST Sheet1 TARGET StateAbr ITEM ItemName.
    Customer.State = StateAbr.
    ItemName = "R" + STRING(Rowi) + "C4".
    DDE REQUEST Sheet1 TARGET ZipCode ITEM ItemName.
    RELEASE Customer.
END.
```

**Note**
For more information on using the DDE protocol to exchange data with non-ABL applications, see *OpenEdge Development: Programming Interfaces*.

**See also**
DDE INITIATE statement

### DDE SEND statement
(Windows only)

Sends a new value to a dynamic data exchange (DDE) server data item associated with the specified DDE conversation.

This statement is supported only for backward compatibility. Use the Component Object Model (COM) instead.

**Note:** Does not apply to SpeedScript programming.
DDE SEND statement

Syntax

```
DDE SEND ddeid SOURCE data ITEM name  
  [ TIME seconds ]  
  [ NO-ERROR ]
```

**ddeid**

An integer expression that equals the channel number of the conversation opened for the specified data item. It is the value returned by the DDE INITIATE statement that opened the conversation.

**SOURCE data**

Specifies the new value for the server data item, where `data` is a character expression that renders the new value in a format acceptable to the data item.

**ITEM name**

Specifies the name of the server data item to receive the new value. The data item `name` is a character expression that identifies the data item according to the conventions of the server application (for example, the row and column coordinates of a worksheet cell, such as R2C1 in Microsoft Excel).

**TIME seconds**

Specifies the maximum number of seconds that the ABL client waits for the DDE SEND statement to complete, where `seconds` is an integer expression. If you do not specify the TIME option or specify a value of 0, the AVM waits indefinitely for the statement to complete.

**NO-ERROR**

By default, if the statement fails to send the value to the data item, the AVM raises the ERROR condition and posts the error to the DDE frame DDE-ERROR attribute. If you specify NO-ERROR, the AVM does not raise the ERROR condition, but does post the error to the DDE frame.

**Example**

The following fragment shows a typical use of the DDE SEND statement. It assumes that the Microsoft Excel application is running, and has created the default Excel worksheet, Sheet1. It then uses the DDE INITIATE statement to open a conversation with Sheet1 as the topic. This allows the AVM to exchange data with the cells of the worksheet. In this example, the fragment assigns column headings to the top row of the first three columns in the worksheet using the DDE SEND statement.

```
DEFINE VARIABLE Sheet1 AS INTEGER NO-UNDO. /* DDE-ID to worksheet topic */
DEFINE VARIABLE DDEframe AS HANDLE NO-UNDO. /* DDE frame handle */
CREATE FRAME DDEframe. /* Create DDE frame */
/* Open a DDE conversation with Sheet1 and assign column headings. */
DDE INITIATE Sheet1 FRAME DDEframe APPLICATION "Excel" TOPIC "Sheet1".
DDE SEND Sheet1 SOURCE "Name" ITEM "R1C1".
DDE SEND Sheet1 SOURCE "YTD Sales" ITEM "R1C2".
DDE SEND Sheet1 SOURCE "State" ITEM "R1C3".
... 
```
DDE TERMINATE statement
(Windows only)

Closes the specified dynamic data exchange (DDE) conversation.

This statement is supported only for backward compatibility. Use the Component Object Model (COM) instead.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```plaintext
DDE TERMINATE ddeid [ NO-ERROR ]
```

**ddeid**

An integer expression that equals the channel number of an open conversation. It is the value returned by the DDE INITIATE statement that opened the conversation.

**NO-ERROR**

By default, if the statement fails to close the conversation, the AVM raises the ERROR condition, and posts the error to the DDE frame DDE-ERROR attribute. If you specify NO-ERROR, the AVM does not raise the ERROR condition but does post the error to the DDE frame.

**Example**

The following fragment shows a typical use of the DDE TERMINATE statement. It assumes that the Microsoft Excel application is running, and has created the default Excel worksheet, Sheet1. It then uses the DDE INITIATE statement to open a conversation with Sheet1 as the topic, returning the channel number of the conversation to the variable, Sheet1. After exchanging data with the worksheet, the example closes the conversation with Sheet1 using the DDE TERMINATE statement.

```plaintext
DEFINE VARIABLE Sheet1 AS INTEGER NO-UNDO. /* DDE-ID to worksheet topic */
DEFINE VARIABLE DDEframe AS HANDLE NO-UNDO. /* DDE frame handle */
CREATE FRAME DDEframe. /* Create DDE frame */
. . .
/* Open a DDE conversation with "Sheet1" and assign column headings. */
DDE INITIATE Sheet1 FRAME DDEframe APPLICATION "Excel" TOPIC "Sheet1".
DDE SEND Sheet1 SOURCE "Name" ITEM "R1C1".
DDE SEND Sheet1 SOURCE "YTD Sales" ITEM "R1C2".
DDE SEND Sheet1 SOURCE "State" ITEM "R1C3".
. . .
DDE TERMINATE Sheet1.
```

**Notes**

- Before closing a DDE conversation, remove all advise links in the conversation using the DDE ADVISE statement.
• Closing this conversation makes ddeid unavailable for further exchanges, but any other conversations open to the same server are still available.

• For more information on using the DDE protocol to exchange data with non-ABL applications, see *OpenEdge Development: Programming Interfaces*.

**See also** DDE ADVISE statement, DDE INITIATE statement

### DECIMAL function

Converts an expression of any data type, with the exception of BLOB, CLOB, and RAW, to a DECIMAL value.

**Syntax**

```
DECIMAL ( expression )
```

**expression**

If expression is a CHARACTER, then it must be valid for conversion into a number. (For example, 1.67 is valid but 1.x3 is not valid.) If expression is LOGICAL, then the result is 0 if expression is FALSE and 1 if expression is TRUE. If expression is a DATE, then the result is the number of days from 1/1/4713 B.C. to that date. If the value of expression is the Unknown value (?), then the result is also the Unknown value (?).

**Example**

The example procedure lets the user enter new values for CreditLimit in a special form. If the user enters the letter a, the procedure uses the standard a credit of 5000; if the user enters b, the procedure uses a value of 2000; if the user presses RETURN, the procedure uses a value of 1000. Otherwise, the user can enter any value for CreditLimit. The DECIMAL function converts the value entered into a decimal value.

**r-decm1.p**

```
DEFINE VARIABLE new-max AS CHARACTER NO-UNDO FORMAT "x(10)".

REPEAT:
  PROMPT-FOR Customer.CustNum WITH FRAME credit.
  FIND Customer USING Customer.CustNum.
  DISPLAY Customer.CustNum Customer.Name Customer.CreditLimit
      WITH FRAME credit DOWN.
  DISPLAY "Enter one of:" SKIP(1)
    "a = 5000" SKIP
    "b = 2000" SKIP
    "RETURN = 1000"
    "A dollar value"
  WITH FRAME vals COLUMN 60.
  SET new-max WITH FRAME credit.
  IF new-max = "a" THEN Customer.CreditLimit = 5000.
  ELSE IF new-max > "0" AND new-max < "999,999.99" THEN
    Customer.CreditLimit = DECIMAL(new-max).
  ELSE Customer.CreditLimit = 1000.
  DISPLAY Customer.CreditLimit WITH FRAME credit.
END.
```

**See also** INTEGER function, STRING function
**DECRYPT function**

Converts encrypted data (a binary byte stream) to its original source format, and returns a MEMPTR containing the decrypted data.

**Note:** You must use the same cryptographic algorithm, initialization vector, and encryption key values to encrypt and decrypt the same data instance.

**Syntax**

```
```

*data-to-decrypt*

The encrypted data to decrypt. The value may be of type RAW or MEMPTR.

*encrypt-key*

An optional RAW expression that evaluates to the encryption key (a binary value) originally used to encrypt the specified data. If you specify the Unknown value (?), the current value of the SYMMETRIC-ENCRYPTION-KEY attribute is used. If the value of the SYMMETRIC-ENCRYPTION-KEY attribute is also the Unknown value (?), the AVM generates a run-time error.

The AVM compares the size of the specified encryption key to the key size specified by the cryptographic algorithm. If the key sizes are inconsistent, the AVM generates a run-time error.

You can use the GENERATE-PBE-KEY function to regenerate the same encryption key originally used to encrypt the specified data as long as you specify the same password string, hash algorithm, number of iterations, and salt value.

**Note:** Do not use the GENERATE-RANDOM-KEY function to generate this encryption key. The random key it generates will always be different than the key originally used to encrypt the specified data.

You are responsible for generating, storing, and transporting this value.

*iv-value*

An optional RAW expression that evaluates to the initialization vector value to use with the specified encryption key in the original encryption operation. If you specify the Unknown value (?), the current value of the SYMMETRIC-ENCRYPTION-IV attribute is used.

*algorithm*

An optional CHARACTER expression that evaluates to the name of the symmetric cryptographic algorithm originally used to encrypt the specified data instance. If you specify the Unknown value (?), the current value of the SYMMETRIC-ENCRYPTION-ALGORITHM attribute is used.
DEFINE BROWSE statement

For a list the supported cryptographic algorithms, see the SYMMETRIC-SUPPORT attribute reference entry.

See also ENCRYPT function, SECURITY-POLICY system handle

DEFINE BROWSE statement

Defines and creates either a read-only or updateable browse widget that is created at compile time for use in one or more procedures, or within a single class.

Note: Does not apply to SpeedScript programming.

Syntax

```
DEFINE { [ NEW ] SHARED | [ PRIVATE ] } BROWSE browse-name
QUERY query-name
   [ SHARE-LOCK | EXCLUSIVE-LOCK | NO-LOCK ] [ NO-WAIT ]
DISPLAY
   { column-list | record [ EXCEPT field ... ] }
   [ browse-enable-phrase ]
   [ browse-options-phrase ]
   [ CONTEXT-HELP-ID expression ]
   [ DROP-TARGET ]
   [ TOOLTIP tooltip ]
```

NEW SHARED BROWSE browse-name

Defines and identifies a browse widget that can be used by other procedures. When the procedure containing this statement ends, the browse is no longer available.

SHARED BROWSE browse-name

Defines and identifies a browse that was created in another procedure with the DEFINE NEW SHARED BROWSE statement.

[ PRIVATE ] BROWSE browse-name

Defines and identifies a browse widget as a class-scoped object. A class-scoped handle-based object is not a member of a class, but provides a resource that is privately available to the class definition similar to a non-shared data element in a procedure definition. The option to specify the PRIVATE access mode is provided for readability. You cannot specify PRIVATE when defining a browse widget as a data element in a method or procedure.

Note: This option is applicable only when defining a class-scoped browse widget in a class definition (.cls) file.
BROWSE browse-name

Defines and identifies a browse widget whose query you can access only within the current procedure, class, or method of a class.

QUERY query-name

The name of the query to browse. You must have previously defined or opened the query.

[ SHARE-LOCK | EXCLUSIVE-LOCK | NO-LOCK ]

Specifies the locking mode for records retrieved by the browse widget. The default locking mode is NO-LOCK. To control locking during preselection for a query associated with a browse widget, use the SHARE-LOCK, EXCLUSIVE-LOCK, or NO-LOCK option in the OPEN QUERY statement that opens the query.

NO-WAIT

Specifies not to wait for a record that is currently locked by another process. Instead, the record in conflict will be made available in NO-LOCK mode and the LOCKED function for that record will return TRUE.

DISPLAY column-list

Specifies the column items to display in the browse. Note that the column-list cannot contain widgets other than fill-ins (default), combo-boxes, and toggle-boxes, and the column-list cannot contain SKIP options.

```
DISPLAY
{ expression
  [ column-format-phase ]
  [ @ base-field ]
  [ view-as-phrase ]
} ...
```

equation

A field name, variable, constant, or expression to display in each iteration of the browse frame.

column-format-phase

Specifies the format for a value displayed in the browse. The column-format-phase is a subset of the Format phrase.
DEFINE BROWSE statement

WIDTH n

Specify a width for the browse column. n represents a multiplier of the average character width of the column font. Specifying a width smaller than the format string creates a scrolling browse cell, if the column is updateable.

For more information on FORMAT strings and label options, see the Format phrase reference entry. The column and label color and font options work like those specified in the browse-options-phrase. If color or fonts are specified with this phrase, they only affect the specific column and override similar options specified in the browse-options-phrase.

@base-field

The base-field must be the name of a field or variable; it cannot be an expression or constant.

The AVM reserves enough space for the base-field to hold the longest format displayed there. All right-justified fields (numeric fields that do not use side labels) are right justified within the reserved area.

To determine the format to use for displaying the expression at the base-field, the AVM looks at the following and uses the first format that applies:

- An explicit format used with the expression.
- If the expression is a character string constant, a format that accommodates that string.
- If the data type of the expression matches that of the base-field, the format of the base-field.
- The standard format of the expression as if it were displayed without a base-field.

view-as-phrase

Specifies the type of widget to use for displaying values in the browse column. This is the view-as-phrase syntax, which is a subset of the VIEW-AS phrase:
DEFINE BROWSE statement

If you do not specify a view-as-phrase, the widget type for the browse column will be a FILL-IN, by default.

For more information, see the VIEW-AS phrase reference entry.

DISPLAY record

Specifies the record you want to display. If you specify a record, all fields from the record are displayed unless you use the EXCEPT option to eliminate specific fields.

See the Record phrase reference entry for more information.

EXCEPT field . . .

Specifies fields that are not displayed in the browse. You can use the EXCEPT option only if you specify a record name in the DISPLAY option.

browse-enable-phrase

Specifies which fields in the column-list are enabled for input.

```
ENABLE
{ { field [ HELP string ]
    [ VALIDATE ( condition, msg-exp ) ]
    [ AUTO-RETURN ]
    [ DISABLE-AUTO-ZAP ]
} . . .
    ALL [ EXCEPT field ]
}
```

List each field or variable from the column-list that you want enabled. Specify ALL to specify every item in the column-list. Use the EXCEPT option to exclude specific items when you use the ALL option.

For each field or variable, you can also specify custom help and validation, as shown in the next two entries.

HELP string

Represents a character string that you want to display whenever the user enters the frame field for the field or variable. When the user leaves the frame field, the AVM removes the help string from the message area. You must enclose the string in quotation marks ("").

VALIDATE ( condition, msg-expression )

Specifies an expression against which you want to validate the data entered in a browse cell. The condition is a Boolean expression (a constant, field name, variable name, or expression) whose value is TRUE or FALSE.

When you use the VALIDATE option to validate a specific cell, any reference to that cell in condition is assumed to be the new input value. For example, in the browse-enable
phrase below, the PromiseDate that is compared to the OrderDate is the new user input, not the existing data:

```plaintext
ENABLE PromiseDate VALIDATE(PromiseDate > OrderDate, "Promise date must be later than order date").
```

To validate a new value against another new value, use the INPUT qualifier, as shown:

```plaintext
ENABLE OrderDate PromiseDate VALIDATE(PromiseDate > INPUT OrderDate, "Promise date must be later than order date").
```

If the value of condition is FALSE, use `msg-expression` to display a specific message. You must enclose `msg-expression` in quotation marks ("").

The AVM processes validation criteria whenever the user attempts to leave the browse cell. If the cell value is not valid, the AVM displays `msg-expression` in the message area, causes the terminal to beep, and does not advance out of the browse cell.

If the user tabs to a cell, makes no changes, and leaves the cell, the AVM does not process the validation criteria specified with the VALIDATE option until you press `GO (F1)`. If the user presses `ENDKEY` or `END-ERROR`, or an error occurs, the AVM does not test the validation criteria specified with the VALIDATE option.

If the input source for the procedure is a table, the AVM validates each input field (except those with a value of "."). If the result of the validation is FALSE, `msg-expression` is displayed and the AVM treats the validation as an error.

To suppress the Data Dictionary validation criteria for a cell, use this VALIDATE option:

```plaintext
VALIDATE(TRUE,""")
```

**AUTO-RETURN**

Indicates whether the AVM behaves as if the user pressed the RETURN key when the user enters the last allowable character in a browse cell of the specified browse column.

**DISABLE-AUTO-ZAP**

Indicates whether the AVM should ignore the value of the browse column’s AUTO-ZAP attribute and assume it is FALSE.

**browse-options-phrase**

Specifies options that affect the browse widget as a whole. The options affect both the layout and the function of the browse widget. Note that you cannot include aggregate-phrases (such as TOTAL, MIN, etc.) in this phrase. This is the syntax for `browse-options-phrase`:
The constant value is the number of rows displayed in the browse and must be at least 2. You can optionally specify the width of the browse, where width is the width of the browse in character units.

A browse-options-phrase must contain a DOWN option or a size-phrase.

size-phrase

Specifies the outer size of the browse border. When this option is used instead of the DOWN option, the AVM determines the number of rows that can be displayed in the browse. Following is the syntax for size-phrase:

{ SIZE SIZE-PIXELS } width BY height

For more information on size-phrase, see the SIZE phrase reference entry.

A browse-options-phrase must contain a DOWN option (optionally with a WIDTH option) or a size-phrase.
DEFINE BROWSE statement

FGCOLOR expression

Specifies the foreground color for the browse in graphical environments, but not the label foreground color. The value of expression must be an integer value that specifies an entry in the color table. This option is ignored in character environments.

BGCOLOR expression

Specifies the background color for the browse in graphical environments. The value of expression must be an integer value that specifies an entry in the color table. This option is ignored in character environments.

DCOLOR expression

Specifies the display color for the browse in character environments. The value of expression must be an integer value that specifies an entry in the color table. This option is ignored in graphical environments.

PFCOLOR expression

Specifies the prompt color for the browse in character environments. The value of expression must be an integer value that specifies an entry in the color table. This option is ignored in graphical environments.

LABEL-FONT constant

Specifies the font of the browse labels.

LABEL-DCOLOR expression

Specifies the display color for the browse labels in character environments. The value of expression must be an integer value that specifies an entry in the color table. This option is ignored in graphical environments.

LABEL-FGCOLOR expression

Specifies the foreground color for the browse labels in graphical environments. The value of expression must be an integer value that specifies an entry in the color table. This option is ignored in character environments.

LABEL-BGCOLOR expression

Specifies the background color for the browse labels in graphical environments. The value of expression must be an integer value that specifies an entry in the color table. This option is ignored in character environments.

MULTIPLE | SINGLE

Specifies whether multiple rows can be selected from the browse or only a single row at one time. The default is SINGLE.

SEPARATORS | NO-SEPARATORS

Specifies whether row and column separators are displayed within the browse. The default is NO-SEPARATORS.
NO-ASSIGN

Disables automatic writes on new data in an updateable browse. If this option is not specified, data entered into an updateable browse is assigned on any action that results in a ROW-LEAVE event. This option is intended for use with user-defined triggers on the ROW-LEAVE event. Essentially, when this option is specified, you must make all data assignments by way of the updateable browse.

```
ON ROW-LEAVE OF my-browse DO:
  IF Customer.State:SCREEN-VALUE IN BROWSE my-browse NE "MA" THEN DO:
    MESSAGE "Customer is out of state."
    RETURN NO-APPLY.
  END.

  /* Your code. Transaction scope is up to you. */

  FIND CURRENT Customer.
  IF NOT CURRENT-CHANGED Customer THEN
    ASSIGN INPUT BROWSE field1 field2 field3 field4.
  ELSE MESSAGE "Record has changed since last read."
  END.
```

In the above example, the code looks for a special case where automatic database writes are not desirable and prevents them. The body of the trigger handles other processing before proceeding to commit the changes. First the trigger refinds the current Customer record and then uses the CURRENT-CHANGED function to see if it has changed while the user was updating the browse cells. If it has not changed, the changes are committed. If it has changed, the trigger would handle that condition, too.

Note that an ASSIGN statement with the INPUT BROWSE option can be mixed with other assignment types, as shown:

```
ASSIGN
  Name
  a = b
  INPUT FRAME my-frame c d
  INPUT BROWSE my-browse order-date promise-date
  INPUT e.
```

NO-ROW-MARKERS

By default, an updateable browse displays row markers, which allow the user to select currently displayed rows in an updateable browse widget. This option prevents row markers from being displayed.

NO-LABELS

Does not display labels above the columns of the browse.

NO-BOX

Does not display a box around the browse. If you do not use this option, the AVM displays a box around the data you are displaying.

If you are sending data to a device other than a terminal and you do not use this option, the AVM omits the sides and bottom line of the box and replaces the top line with blanks.
DEFINE BROWSE statement

FONT constant

Specifies the font of the browse. Labels also use this font, unless otherwise specified.

title-phrase

Displays a title as part of the top line of the box around the browse. For example:

```
TITLE [ DCOLOR expression ] [ title-string ]
```

The `title-string` is a constant, field name, variable name, or expression whose result is a character value. The `expression` is the value you want to display as a title. If `title-string` is a constant character string, it must be surrounded by quotes (""). The AVM automatically centers `title-string` in the top line of the browse box.

You can use the DCOLOR option to specify the color of the title under a character user interface.

You cannot specify the title color or font of a browse in a graphical interface.

NO-VALIDATE

Tells the AVM to ignore the validations conditions in the schema for all fields in the browse.

Since browses do not inherit the NO-VALIDATE option from a parent frame, if you want a browse to have this option, you must specify it explicitly.

NO-SCROLLBAR-VERTICAL | SCROLLBAR-VERTICAL

Indicates whether the browse displays a vertical scrollbar. The default is to display the vertical scrollbar.

ROW-HEIGHT-CHARS | ROW-HEIGHT-PIXELS row-height

An integer representing the browse’s row height in either characters or pixels.

This option applies to graphical interfaces only.

FIT-LAST-COLUMN

Allows the browse to be displayed so that there is no empty space to the right and no horizontal scroll bar by potentially widening or shrinking the last browse column’s width.

This option applies to graphical interfaces only.

When this option is specified, and the last browse column can be fully or partially displayed in the browse’s viewport, then the last browse column’s width is adjusted so that it fits within the viewport with no empty space to its right and no horizontal scroll bar.

If the last browse column is fully contained in the viewport with empty space to its right, it grows so that its right edge is adjacent to the vertical scroll bar.

If the last browse column extends outside the viewport, it shrinks so its right edge is adjacent to the vertical scroll bar and the horizontal scroll bar is not needed.
The default value is FALSE.

**Note:** The FIT-LAST-COLUMN option performs the same function as the EXPANDABLE option. Progress Software Corporation recommends that you use the FIT-LAST-COLUMN option instead of the EXPANDABLE option. This recommendation includes replacing EXPANDABLE with FIT-LAST-COLUMN in your current code.

**EXPANDABLE**

If you set a browse’s EXPANDABLE option to TRUE, the AVM extends the right-most browse column horizontally to the browse’s right edge, if necessary, to cover any white space that might appear there — unless you explicitly set the width of the right-most browse column using the WIDTH-CHARS or WIDTH-PIXELS option. The expansion of the right-most browse column might occur anytime the browse or another browse column is resized.

The right-most browse column expands only when there is no horizontal scroll bar. This is because when there is a horizontal scroll bar, no white space appears between the right edge of the right-most browse column and the right edge of the browse.

**Note:** The EXPANDABLE option performs the same function as the FIT-LAST-COLUMN option. Progress Software Corporation recommends that you use the FIT-LAST-COLUMN option instead of the EXPANDABLE option. This recommendation includes replacing EXPANDABLE with FIT-LAST-COLUMN in your current code.

**NO-EMPTY-SPACE**

Allows the browse to display with no empty space to the right and no horizontal scroll bar.

You cannot specify both NO-EMPTY-SPACE and FIT-LAST-COLUMN for the DEFINE BROWSE statement. If you specify both, the compiler displays an error message. If you set either the NO-EMPTY-SPACE option or the DEFINE BROWSE option to TRUE and one of them is already TRUE, a warning message displays at run time.

**NO-AUTO-VALIDATE**

Tells ABL to compile into the code all relevant validations it finds in the OpenEdge Data Dictionary, but to run the validations only when the code for a browse or a browse column specifically invokes the VALIDATE() method.

**CONTEXT-HELP-ID expression**

An integer value that specifies the identifier of the help topic for this browse in a help file specified at the session, window, or dialog box level using the CONTEXT-HELP-FILE attribute.

**DROP-TARGET**

Indicates whether the user can drop a file onto the object.
TOOLTIP tooltip

Allows you to define a help text message for a browse widget. The AVM automatically displays this text when the user pauses the mouse pointer over a browse widget for which a ToolTip is defined. You can add or change the TOOLIP option at any time.

If TOOLIP is set to "" or the Unknown value (?), then the ToolTip is removed from the browse. No ToolTip is the default. ToolTips are supported in Windows only.

Examples

This procedure sets up a read-only browse widget for the Customer table. The browse displays the CustNum and Name fields. A separate frame, f2, displays more information on the currently chosen Customer.

```
rBrowse.p
```

```
DEFINE QUERY q1 FOR Customer.
DEFINE BROWSE b1 QUERY q1 DISPLAY CustNum Name
  WITH 17 DOWN TITLE "Customer Browse".

DEFINE FRAME f1 b1
  WITH SIDE-LABELS AT ROW 2 COLUMN 2.
DEFINE FRAME f2
  WITH 1 COLUMNS AT ROW 2 COLUMN 38.

ON VALUE-CHANGED OF b1 DO:
  DISPLAY Customer EXCEPT Customer.Comments WITH FRAME f2.
END.

OPEN QUERY q1 FOR EACH Customer.
ENABLE b1 WITH FRAME f1.
APPLY "VALUE-CHANGED" TO BROWSE b1.
WAIT-FOR WINDOW-CLOSE OF CURRENT-WINDOW.
```

The VALUE-CHANGED event occurs each time the user selects a row within the browse widget. The associated database record is automatically placed into the record buffer. The trigger on the VALUE-CHANGED event displays that record in frame f2.

The APPLY statement causes the first Customer record to display before the user selects a record.

The second example sets up an updateable browse that displays some fields from the Customer table. Select a row marker to select a row. Select a cell to edit it. Select a column label to initiate a search. (The trigger on ROW-LEAVE is only necessary because the NO-ASSIGN option prevents automatic commitment of the data when the user leaves a row.)
**DEFINE BROWSE statement**

**Notes**

- You cannot define a SHARED or NEW SHARED browse widget in a persistent procedure. If you do, ABL raises ERROR on the RUN statement that creates the procedure.

- You cannot define a SHARED or NEW SHARED browse widget in a class definition (.cls) file. If you do, ABL generates a compilation error.

- The vertical scrollbar is displayed with the browse by default in Windows interfaces. It may be removed by setting the SCROLLBAR-VERTICAL attribute to FALSE or by specifying NO-SCROLLBAR-VERTICAL in the DEFINE BROWSE statement. If the horizontal scrollbar is needed, it is provided by default.

- The vertical scrollbar thumb size reflects the percentage of rows that are displayed in the viewport relative to the number of rows in the results list. If all the rows have not yet been read into the results list, the AVM uses the MAX-DATA-GUESS attribute to estimate the total size.
• You must put the browse into a frame on the same procedure level on which the browse is defined. For example, you cannot define a browse in an outer procedure and then display it in a frame defined within an internal procedure.

• You cannot display a browse widget in a down frame. The AVM automatically converts any frame containing a browse to a 1 down frame.

• You can modify the field values displayed in the current iteration of a browse by using the WITH BROWSE option of the DISPLAY statement. For example:

```assembly
DISPLAY { field | { value @ field } } ... WITH BROWSE browse
```

• The browse widget has built-in support for the HOME, END, PAGE-UP, and PAGE-DOWN key functions.

• You can specify an application-defined widget ID for a compile-time defined browse widget using the `form-item` phrase in either the FORM statement or the DEFINE FRAME statement. See the FORM statement and DEFINE FRAME statement reference entries for more information.

• ABL treats the query associated with a browse as a scrolling query. You do not have to specify SCROLLING in the DEFINE QUERY statement.

• When you execute an OPEN QUERY or REPOSITION statement for the query associated with the browse, the browse is automatically adjusted to remain in sync with the query. However, when you execute a GET statement, the browse is not adjusted. You can use the GET statement to perform background processing without affecting the browse, but you must execute a REPOSITION statement to put the query and browse back in sync.

• The record locking behavior specified for a query in the DEFINE BROWSE statement overrides the record locking behavior specified with the OPEN QUERY statement. The default record locking behavior of a browse widget is NO-LOCK. The default record locking behavior of a query defined with the OPEN QUERY statement is SHARE-LOCK. If you define a query and a browse widget for the query without explicitly defining record locking behavior, the query will have the NO-LOCK behavior.

• For an updateable browse, the AVM re-gets the record with a SHARE-LOCK when the user first edits a row, if it initially has a NO-LOCK. The user then can make changes to the updateable cells in the row. When the user leaves a row with changes (moves to a new row or another widget), the AVM starts a transaction and gets the record with EXCLUSIVE-LOCK and NO-WAIT. If the AVM gets the record, the record is updated, the record is disconnected (removes the lock), the transaction ends, and the lock is downgraded to its original status. If the get record with EXCLUSIVE-LOCK fails, the transaction is backed out, an error message is displayed, and focus remains with the edited browse row with the changed data. To redisplay the original data, use the DISPLAY...WITH BROWSE statement.

• All LEAVE triggers for a browse row execute before the row changes are committed. If the LEAVE trigger returns a NO-APPLY, the changes are not committed.

• It is also possible to use an updateable browse to add new records and delete old ones.
• Browse widgets in Windows have user search capabilities. Special events allow you to extend these capabilities.

• To select more than one row in a browse widget, press **CTRL** and then click on the rows you want to select.

• When an updateable browse enters edit mode, all selected records are deselected. Essentially, a browse in edit mode ignores multiple selections.

• The ADD-CALC-COLUMN, ADD-COLUMNS-FROM and ADD-LIKE-COLUMN methods may be used on a compile-time defined browse to add a dynamic browse column. If a dynamic browse column in a compile-time defined browse is made updateable, the browse is changed to a NO-ASSIGN browse and you become responsible for any database update associated with it.

• The browse’s QUERY attribute can now be set to the Unknown value (?). If this is done, all browse columns are removed.

• The browse’s QUERY attribute can now be changed to any query. Previously, the new query had to have the same underlying fields as the original query. If the new query is different, all browse columns are removed. You must specify new columns with the ADD-CALC-COLUMN, ADD-COLUMNS-FROM, and ADD-LIKE-COLUMN methods.

**See also** ADD-CALC-COLUMN( ) method, ADD-COLUMNS-FROM( ) method, ADD-LIKE-COLUMN( ) method, Class-based data member access, CLOSE QUERY statement, CREATE BROWSE statement, CURRENT-CHANGED function, CURRENT-RESULT-ROW function, DEFINE QUERY statement, DISPLAY statement, FIND statement, FORM statement, Format phrase, Frame phrase, GET statement, NUM-RESULTS function, OPEN QUERY statement, RUN statement

**DEFINE BUFFER statement**

ABL provides you with one default buffer for each table or temp-table that you use in a procedure or class. ABL uses that buffer to store one record at a time from the table as the records are needed during the procedure or class. If you need more than one record or buffer at a time for a table, you can use this statement to define alternate buffers that are created at compile time for use in one or more procedures, or within a single class or class hierarchy.

**Syntax**

```
DEFINE { [ [ NEW ] ] [ SHARED ] } [ [ PRIVATE ] | [ PROTECTED ] ] [ [ STATIC ] ] }
BUFFERS [ [ NEW ] ] buffer-name
FOR [ [ TEMP-TABLE ] ] table-name
[ [ PRESELECT ] ] [ [ LABEL label-name ] ]
[ [ NAMESPACE-URI namespace ] ] [ [ NAMESPACE-PREFIX prefix ] ]
[ [ XML-NODE-NAME node-name ] ]
```

**NEW SHARED BUFFER buffer-name**

Defines and identifies a buffer that can be used by other procedures. When the procedure using this statement ends, the buffer is no longer available.
DEFINE BUFFER statement

SHARED BUFFER buffer-name

Defines and identifies a buffer that was created in another procedure with the DEFINE NEW SHARED BUFFER statement.

[ PRIVATE | PROTECTED ] [ STATIC ] BUFFER buffer-name

Defines and identifies a buffer as a data member of a class, and optionally specifies an access mode (PRIVATE or PROTECTED) and scope (instance or STATIC) for that data member. You cannot specify these options when defining a buffer as a data element of a method (including constructors, destructors, and property accessors) or a procedure.

Note: The specified options are applicable only when defining a data member for a class in a class definition (.cls) file. Note also that you cannot shadow (override) the definition of a given buffer data member in a class hierarchy.

PRIVATE buffer data members can be accessed only by the defining class. PROTECTED buffer data members can be accessed by the defining class and any of its derived classes. The default access mode is PRIVATE. When you reference a buffer from another data member definition (such as a query) defined in the same class or class hierarchy, the access mode of the buffer cannot be more restrictive than the access mode of the referencing data member.

A buffer defined with the STATIC option is a static data member of the class type for which it is defined and is scoped to the ABL session where it is referenced. ABL creates one copy of the specified class static buffer on first reference to the class type, and ABL creates only one such copy for any number of instances of the class that you create. You can directly reference an accessible static buffer data member from any other static or instance class member defined in the same class or class hierarchy.

Without the STATIC option, ABL creates an instance buffer data member that is scoped to a single instance of the class where it is defined. ABL creates one copy of the specified instance buffer for each such class instance that you create. You cannot directly reference an instance buffer data member from a STATIC class member definition defined within the same class or class hierarchy.

Within a class, ABL defines the default buffer for any database table as a PRIVATE instance buffer. Thus, for example, you can only access the default buffer for the Customer table of the sports2000 database wherever a PRIVATE instance buffer can be accessed. Otherwise, you must define an alternate buffer data member for the table with an appropriate access mode and scope.

For more information on accessing buffers of different access modes and scopes, see the reference entry for Class-based data member access.

Note: Members of a class are grouped into six namespaces, including buffers/temp-tables, methods, variables/properties/events, ProDataSets, queries, and data-sources. Buffers and temp-tables defined as members of a class share the same namespace. There can be only one class member in this namespace with a given name.

For more information on where and how to define data members in a class, see the CLASS statement reference entry.
DEFINE BUFFER statement

BUFFER buffer-name

Defines and identifies a buffer whose records you can access only within the current procedure, method of a class (including constructors, destructors, and property accessors), or as a PRIVATE data member of a class.

FOR TEMP-TABLE table-name

Identifies the name of the table for which you are defining an additional buffer. This can also be the built-in buffer name, proc-text-buffer, to define a buffer that returns table rows from a stored procedure.

To define a buffer for a table defined for multiple databases, you might have to qualify the table name with the database name. See the Record phrase reference entry for more information.

Use the TEMP-TABLE option to define a buffer for a temp-table when the temp-table has the same name as a database table. Otherwise, ABL associates the buffer with the database table by default.

If you define the buffer as static, and table-name is the name of a temp-table, the temp-table must also be defined as a static member of a class.

PRESELECT

If you use the PRESELECT option with a DO or REPEAT block, the AVM creates an internal list of the records selected. The PRESELECT option tells the AVM to apply that internal list to the buffer you define. You can also use the PRESELECT option in the DEFINE SHARED BUFFER statement.

LABEL label-name

Specifies a label for the buffer. This label is used in error messages in place of the buffer name.

NAMESPACE-URI namespace

An optional CHARACTER constant that specifies the URI for the namespace of the buffer object.

NAMESPACE-PREFIX prefix

An optional CHARACTER constant that specifies the namespace prefix associated with the NAMESPACE-URI.

XML-NODE-NAME node-name

An optional CHARACTER constant that specifies the name of the XML element representing the temp-table buffer in an XML Document. The default is buffer-name.

Examples

This procedure allows the user to create a new Customer record. Initially, the City, State, and Country fields are not shown. After the user enters a PostalCode value, the procedure searches for an existing Customer with the same postal code. If such a Customer is found, the City, State, and Country values from that record are displayed in the fields for the new record. The user can then update those fields.
The following gather a group of records so that the user can enter any table name and any set of record selection criteria and then look at the records in the table that meet those criteria:

```assembly
DEFINE VARIABLE fname AS CHARACTER NO-UNDO FORMAT "x(12)" LABEL "Table name".
DEFINE VARIABLE conditions AS CHARACTER NO-UNDO FORMAT "x(60)" LABEL "Conditions".
REPEAT:
   /* Get the name of a table and, optionally, some record selection criteria */
   UPDATE fname COLON 12 conditions COLON 12 WITH SIDE-LABELS 1 DOWN.
   HIDE ALL.
   IF conditions <> "" THEN
      /* Pass the table name and the record selection criteria as parameters */
      RUN r-defb3.p fname "WHERE" conditions.
   ELSE
      RUN r-defb3.p fname.
   END.
END.
```

The `r-defb2.p` procedure gets the name of a table (such as Customer) and a condition (such as CreditLimit > 4000) and passes them as arguments to the `r-defb3.p` procedure.
r-defb3.p

```pascal
DEFINE NEW SHARED BUFFER rec FOR \{1\} PRESELECT.

DEFINE VARIABLE flist AS CHARACTER NO-UNDO EXTENT 12.
DEFINE VARIABLE ix AS INTEGER NO-UNDO.

/* Look in _File for the table named in the fname variable */
FIND _File "{1}".

/* Store the table's field names in the first array */
FOR EACH _Field OF _File USE-INDEX _Field-Posit:
  IF i >= 12 THEN LEAVE.
  i = i + 1.
  flist[i] = _Field._Field-Name.
END.

/* Preselect records */
DO PRESELECT EACH rec \{2\} \{3\} \{4\} \{5\} \{6\} \{7\} \{8\} \{9\} \{10\} \{11\} \{12\}:
  /* Pass the filenames and all field names to r-defb4.p */
END.
```

The r-defb3.p procedure:

- Lets you view the OpenEdge Data Dictionary. The _File table contains a record for each of your database tables.

- Lets you look up a record for a Customer table. For example, the user supplies Customer as a table name; the FIND statement in the r-defb3.p procedure translates to FIND _File Customer. The FIND statement finds, in _File, the record for the Customer table.

- Lets you view the _Field table in the OpenEdge Data Dictionary. The _Field table contains a single record for each of your database fields. The FOR EACH statement reads the name of each of those fields into the first array variable. If the table name is Customer, the first array variable contains the names of each of the fields in the Customer table.

- Lets you select records. For example, the user supplies the condition `CreditLimit > 4000` in the table name. The DO PRESELECT EACH rec statement translates to DO PRESELECT EACH rec WHERE MaxCredit > 4000. The AVM goes through the Customer table and selects the records that meet the criteria. It creates a temp-table containing a pointer to each of those records. This list of preselected records is associated with the rec buffer.

- Runs r-defb4.p, passing the table name (Customer) and the names of all of the fields in that table.

The r-defb4.p procedure has access to the rec buffer (and through it to the set of preselected records). This connection is made by using PRESELECT on the DEFINE SHARED BUFFER statement. The r-defb4.p procedure displays those records.
DEFINE BUFFER statement

Because r-defb3.p and r-defb4.p use run-time argument passing, they cannot be precompiled. Having separate versions of r-defb4.p for each table and running the appropriate one in r-defb3.p, should improve response time. This approach is worthwhile if there are many lines of code in r-defb4.p.

If you define a NEW SHARED BUFFER in a procedure, then call a subprocedure that puts a record into that buffer, and display the buffer in the main procedure, the AVM displays this message:

```
Missing FOR, FIND or CREATE for Customer.
```

This message is displayed when the FIND statement is not in the main procedure:

```c
/* Main procedure */
DEFINE NEW SHARED BUFFER x FOR Customer.
RUN proc2.p.
DISPLAY x.
```

```c
/* proc2.p */
DEFINE SHARED BUFFER x FOR Customer.
FIND FIRST x.
```

To avoid this, explicitly scope the Customer record to the main procedure block. For example:

```c
/* Main procedure */
DEFINE NEW SHARED BUFFER x FOR Customer.
RUN proc2.p.
DO FOR x:
   DISPLAY x.
END.
```

For examples of instance and static buffer data member definitions, see the descriptions of r-CustObj.cls, r-CustObjStatic.cls, and r-CustObjAbstract.cls in the CLASS statement reference entry.

Notes
- You cannot define a SHARED or NEW SHARED buffer in a class definition (.cls) file. If you do, ABL generates a compilation error.
A buffer can be compile-time defined (often referred to as a *static* buffer object), where the buffer is defined and created at compile time using this statement, or it can be run-time defined (often referred to as a *dynamic* buffer object), where the buffer is defined and created at run time using the `CREATE BUFFER` statement and buffer object handle operations. A compile-time defined buffer can also be defined as a static data member of a class. In this case, it is a static buffer object that is also a class static data member.

Every statement that uses a table name to refer to the default buffer can also use the name of a defined alternate buffer.

All data definitions and field names are associated with a table, not a buffer. Data definitions and field names remain the same no matter what buffer you use.

If two buffers contain the same record, a change to one of the buffers is automatically reflected in the other buffer.

You can pass a buffer as a parameter to a procedure.

A SHARED buffer remains in scope for an instance of a persistent procedure until the instance is deleted. This is true even if the original procedure that defined the buffer as NEW SHARED goes out of scope while the procedure instance remains persistent.

If a trigger or internal procedure of a persistent procedure executes an external subprocedure that defines a SHARED buffer, ABL includes the persistent procedure in the resolution of the corresponding NEW SHARED buffer as though the procedure were on the procedure call stack.

If you define a temp-table with the same name as a database table and you then define a buffer for that table name, by default the buffer will be associated with the database table, not with the temp-table. Use the TEMP-TABLE option to define a buffer for a temp-table when the temp-table has the same name as a database table.

For more information on using the built-in buffer name proc-text-buffer, see the OpenEdge DataServer Guides (*OpenEdge Data Management: DataServer for Microsoft SQL Server*, *OpenEdge Data Management: DataServer for ODBC*, and *OpenEdge Data Management: DataServer for Oracle*).

---

**DEFINE BUTTON statement**

The `DEFINE BUTTON` statement defines a push button that is created at compile time for use within the current procedure or class.

**Note:**  
Does not apply to SpeedScript programming.
DEFINE BUTTON statement

Syntax

```
DEFINE [ PRIVATE ] BUTTON button
    [ AUTO-GO | AUTO-ENDKEY ]
    [ DEFAULT ]
    [ BGCOLOR expression ]
    [ CONTEXT-HELP-ID expression ]
    [ DCOLOR expression ]
    [ DROP-TARGET ]
    [ FGCOLOR expression ]
    [ FONT number ]
    [ IMAGE-DOWN image-phrase ]
    [ IMAGE | IMAGE-UP ] image-phrase ]
    [ IMAGE-INSENSITIVE image-phrase ]
    [ MOUSE-POINTER name ]
    [ LABEL label ]
    [ LIKE button ]
    [ PFCOLOR expression ]
    [ size-phrase ]
    [ NO-FOCUS [ FLAT-BUTTON ] ]
    [ NO-CONVERT-3D-COLORS ]
    [ TOOLIP tooltip ]
    { [ trigger-phrase ] }
```

[ PRIVATE ] BUTTON button

Defines and identifies a button widget as a class-scoped object. A class-scoped handle-based object is not a member of a class, but provides a resource that is privately available to the class definition similar to a non-shared data element in a procedure definition. The option to specify the PRIVATE access mode is provided for readability. You cannot specify PRIVATE when defining a button widget as a data element in a method or procedure.

**Note:** This option is applicable only when defining a class-scoped button widget in a class definition (.cls) file.

BUTTON button

Defines and identifies a button widget for access only within the current procedure, class, or method of a class.

AUTO-END-KEY

Specifies that when you choose this button, the AVM applies the ENDKEY event to the frame.

AUTO-GO

Specifies that when you choose this button, the AVM applies the GO event to the frame.
DEFINE BUTTON statement

DEFAULT

Specify DEFAULT to indicate that the button is a default button. A default button is one that handles all RETURN events when no other RETURN-enabling widget in the frame or dialog box has focus. RETURN-enabling widgets include any field-level widget for which a RETURN trigger is defined, or any button, whether or not it has a trigger defined. Thus, if a button has focus, that button handles the next RETURN event. If any other field-level widget without a RETURN trigger has focus, the default button handles the next RETURN event.

To make the button the default button for the frame in which it resides, you must also set the frame’s DEFAULT-BUTTON option.

BGCOLOR expression

Supported only for backward compatibility.

CONTEXT-HELP-ID expression

An integer value that specifies the identifier of the help topic for this button in a help file specified at the session, window or dialog box level using the CONTEXT-HELP-FILE attribute.

DCOLOR expression

Specifies the display color for the button in character interfaces. This option is ignored in graphical interfaces.

FGCOLOR expression

Supported only for backward compatibility.

FONT number

Specifies the font for the button label. The value number must be an expression that resolves to an integer value. That integer must be associated with a specific font in your system environment files.

\{ IMAGE | IMAGE-UP \} image-phrase

An image that you want to appear within the button when the button is in its up state. If the image does not have a down state, for code readability you might want to use the IMAGE option instead of the IMAGE-UP option.

The IMAGE | IMAGE-UP image-phrase option is ignored in character interfaces.

The syntax of image-phrase is as follows:

```
FILE name
  [ \{ IMAGE-SIZE | IMAGE-SIZE-CHARS | IMAGE-SIZE-PIXELS \}
    width BY height
  ]
  [ FROM \{ \{ X n Y n \} | \{ ROW n COLUMN n \} \} ]
```

For more information on this syntax, see the Image phrase reference entry.
DEFINE BUTTON statement

IMAGE-DOWN  image-phrase

An image that you want to appear within the button when the button is in its down state. The IMAGE-DOWN option is ignored in character interfaces.

For more information, see the Image phrase reference entry.

Note: The AVM draws the 3D effect only if a button has an up image, but no down image.

IMAGE-INSENSITIVE  image-phrase

An image you want to appear within the button when the button is in its insensitive (disabled) state. This option is ignored in character interfaces.

For more information, see the Image phrase reference entry.

MOUSE-POINTER  name

Specifies the mouse pointer for the button. The character value name is either the name of a predefined ABL pointer, or the name of a Windows .cur file that defines a pointer or an .ani file that contains an animated cursor.

LABEL  label

The label displayed on the button. The name should describe the action invoked when the button is chosen. The value of label must be a string enclosed in quotes. The default label is the button name. If you use the LIKE button option and you do not use the LABEL option, the button inherits the label of the button you name.

You can indicate a character within the label to be used as a navigation mnemonic in Windows. Indicate the character by preceding it with an ampersand (&). When the button is displayed, the mnemonic is underlined. The user can choose the button by pressing ALT and the underlined letter. If you specify more than one button with the same mnemonic, the AVM transfers focus to each of these in tab order when you make a selection.

To include a literal ampersand within a label, specify a double ampersand (&&).

LIKE  button

Indicates the name of a defined button whose characteristics you want to use for a new button. If you name a button with this option, you must have defined that button earlier in the procedure. You can override the label, image, and on phrase by using the LABEL, IMAGE, and on-phrase options. If you do not use these options, the button takes on the characteristics of the button you name.

PFCOLOR  expression

Specifies the prompt-for color for the button in character interfaces. This option is ignored in graphical interfaces.

size-phrase

Specifies the outside dimensions of the button widget. Following is the syntax for size-phrase:
If you specify SIZE or SIZE-CHARS, the units are characters; if you specify SIZE-PIXELS, the units are pixels. For character units, the values width and height must be decimal constants; for pixel units, they must be integer constants. For more information, see the SIZE phrase reference entry.

If no size is specified, the AVM calculates a default size for the button. This calculation adds the button’s border thickness (that is, the combination of 3D shadows and highlights, and the focus rectangle) to the up image size defined by the IMAGE | IMAGE-UP image-phrase option. However, the thickness of the border depends on whether the button has dual images (up and down images) and whether it is a FLAT-BUTTON or NO-FOCUS button.

Table 27 explains how many pixels the image size expands based on the button size.

Table 27: Determining button border thickness

<table>
<thead>
<tr>
<th>Button image</th>
<th>NO-FOCUS status</th>
<th>FLAT-BUTTON status</th>
<th>Border thickness</th>
</tr>
</thead>
<tbody>
<tr>
<td>Up image only</td>
<td>No</td>
<td>No</td>
<td>7 pixels (2 pixels for the focus rectangle, 5 pixels for the 3D shading)</td>
</tr>
<tr>
<td>Up and down image</td>
<td>No</td>
<td>No</td>
<td>4 pixels (4 pixels for the focus rectangle, 0 pixels for the 3D shading)</td>
</tr>
<tr>
<td>Up image only</td>
<td>Yes</td>
<td>No</td>
<td>5 pixels (0 pixels for the focus rectangle, 5 pixels for the 3D shading)</td>
</tr>
<tr>
<td>Up and down image</td>
<td>Yes</td>
<td>No</td>
<td>0 pixels (ABL expects the specified image to include a border)</td>
</tr>
<tr>
<td>Up image only</td>
<td>Yes</td>
<td>Yes</td>
<td>2 pixels</td>
</tr>
<tr>
<td>Up and down image</td>
<td>Yes</td>
<td>Yes</td>
<td>2 pixels</td>
</tr>
</tbody>
</table>

NO-FOCUS [ FLAT-BUTTON ]

Specifies that the button should not accept focus. A button for which the NO-FOCUS attribute is defined will not take focus when the mouse is clicked on it, and it will not accept keyboard input. Also, the AVM will not generate ENTRY or LEAVE events for the button. NO-FOCUS buttons behave similarly to standard Windows toolbar buttons. The NO-FOCUS option is supported in Windows only.

A button with the NO-FOCUS attribute is not added to its parent frame’s tab order. However, if the NO-FOCUS attribute is switched from TRUE to FALSE before the button is realized, the button is added to the end of its parent frame’s tab order. Switching the
NO-FOCUS attribute from FALSE to TRUE before realization removes the button from its parent frame’s tab order.

**Note:** If a frame that contains a NO-FOCUS button does not itself have focus, the frame does not receive focus when the button is pushed. In this situation, frame entry or leave events are not generated. Focus stays on the current widget when a NO-FOCUS button is pushed, even across multiple frames in a window.

**FLAT-BUTTON**

A flat button is a new style of button which is two-dimensional until the mouse passes over it, at which time, a 3D border appears.

**NO-CONVERT-3D-COLORS**

Specifies that the colors of the button’s images (that is, up, down, and insensitive) are not converted to the system 3D colors. By default, the AVM converts shades of gray in an image to the corresponding system 3D color. Using the NO-CONVERT-3D-COLORS option overrides this default behavior. The NO-CONVERT-3D-COLORS option is supported in Windows only.

Table 28 describes the conversion process.

**Table 28: 3D-color conversions for buttons**

<table>
<thead>
<tr>
<th>If the color is...</th>
<th>And the original Red-Green-Blue (RGB) color value is...</th>
<th>Then the new converted system color is...</th>
</tr>
</thead>
<tbody>
<tr>
<td>White</td>
<td>(255, 255, 255)</td>
<td>System button highlight color</td>
</tr>
<tr>
<td>Light Gray</td>
<td>(192, 192, 192)</td>
<td>System button face color</td>
</tr>
<tr>
<td>Dark Gray</td>
<td>(128, 128, 128)</td>
<td>System button shadow color</td>
</tr>
<tr>
<td>Black</td>
<td>(0, 0, 0)</td>
<td>System button text color</td>
</tr>
</tbody>
</table>

During a session, if Windows notifies the AVM that the system colors have changed, the button’s images are re-loaded and converted to the new system colors, unless the NO-CONVERT-3D-COLORS option is specified.

**TOOLTIP **`tooltip`**

Allows you to define a help text message for a button. The AVM automatically displays this text when the user pauses the mouse pointer over the button.

You can add or change the TOOLTIP option at any time. If TOOLTIP is set to "" or the Unknown value (?)\), then the ToolTip is removed from the button. No ToolTip is the default. ToolTips are supported in Windows only.

**DROP-TARGET**

Indicates whether you want to be able to drop a file onto the object.
**DEFINE BUTTON statement**

*trigger-phrase*

Specifies application triggers for the button.

For more information, see the Trigger phrase reference entry.

**Example**

This procedure defines two buttons, positions the buttons within a form, assigns triggers to the buttons with ON statements, and enables the buttons by referencing them in an ENABLE statement:

```plaintext
r-button.p
DEFINE BUTTON more-button LABEL "More".
DEFINE BUTTON next-button LABEL "Next".

FORM more-button next-button
  WITH FRAME but-frame ROW 1.

FORM Customer.CustNum Customer.Name
  WITH FRAME brief ROW 4.

FORM Customer EXCEPT Customer.CustNum Customer.Name
  WITH FRAME full ROW 7.

ON CHOOSE OF more-button
  DISPLAY Customer EXCEPT Customer.CustNum Customer.Name WITH FRAME full.

ON CHOOSE OF next-button DO:
  HIDE FRAME full.
  FIND NEXT Customer NO-ERROR.
  DISPLAY Customer.CustNum Customer.Name WITH FRAME brief.
  END.

FIND FIRST Customer.
DISPLAY Customer.CustNum Customer.Name WITH FRAME brief.

ENABLE more-button next-button WITH FRAME but-frame.
WAIT-FOR WINDOW-CLOSE OF CURRENT-WINDOW.
```

When the procedure is run, the first Customer’s number and name are initially displayed. The user can choose either the MORE button to see the entire Customer record or the NEXT button to see the next Customer’s number and name.

The following example sets up a browse that allows you to drop a file on the browse:

```plaintext
DEFINE BUTTON button-1 LABEL ''Drop Here'' DROP-TARGET.
```

**Notes**

- When a frame receives a default RETURN event, it actually sends a CHOOSE event to the default button.

- To create the compile-time defined button you are defining, you must define a compile-time defined frame that contains the button. Each frame you define that contains the same button creates an additional instance of that button. The handle for a compile-time defined button is not available until the button is created.

- You must enable a button to make it available to the user. You can enable a button by setting its SENSITIVE attribute or by referencing it in an ENABLE or UPDATE statement.
DEFINE DATASET statement

- On a character-based terminal, a button appears as the label enclosed in angle brackets (< >). The user can move the mouse pointer to the button by pressing TAB or arrow keys. The user can then choose the button by pressing SPACEBAR or RETURN.

- You can specify an application-defined widget ID for a compile-time defined button widget using the form-item phrase in either the FORM statement or the DEFINE FRAME statement. See the FORM statement and DEFINE FRAME statement reference entries for more information.

- To make an application portable between graphical and character environments, you can specify an image and a label for a button. In graphical environments, the image is used and the label is ignored; in character environments, the label is used and the image is ignored.

- If you specify a size for a button, the button is not affected by changes to the size of any contained image. If you do not specify a size for the button, the button changes size to fit the image.

- In Windows, ABL supplies the following prepackaged images for the up, down, left, and right arrows: btn-up-arrow, btn-down-arrow, btn-left-arrow, and btn-right-arrow. Specify one of these items in place of a filename.

  Use these values for the IMAGE-UP option. Doing so makes the prepackaged image available to ABL in its up, down, and insensitive state, without specifying the IMAGE-DOWN and the IMAGE-INSENSITIVE options. You will also get appropriately sized arrows based on your screen resolution.

- You can apply entry to a NO-FOCUS button programmatically. The AVM does not report an error. However, the button will not respond to keyboard activity.

- The AVM draws the 3D effect only if a button has an up image, but no down image. If the button has both an up image and a down image, the AVM does not draw the 3D effect; the images, themselves, should be drawn with a 3D effect.

- The AVM only performs the color conversion process on bitmaps (.bmp files) that contain 256 or fewer colors. However, you might consider using 16-color bitmaps because only the first sixteen entries in the bitmap’s color table will be converted.

- Icon colors (.ico files) are not converted, even if CONVERT-3D-COLORS is TRUE. To ensure that an icon will be displayed properly on a button, draw icons with a transparent background.

**See also** Class-based data member access, FORM statement, Image phrase

**DEFINE DATASET statement**

Defines a ProDataSet object that is created at compile time, and allows you to identify the temp-table buffers it incorporates and define the data relations between those buffers. This statement defines the ProDataSet for use in one or more external procedures, or within a single class or class hierarchy.
DEFINE DATASET statement

**Syntax**

```
DEFINE { [ NEW ] [ SHARED ] | [ PRIVATE | PROTECTED ] [ STATIC ] } DATASET dataset-name
[ [ NAMESPACE-URI namespace ] [ NAMESPACE-PREFIX prefix ] ]
[ [ XML-NODE-NAME node-name ] [ SERIALIZE-NAME serialize-name ] ]
[ [ REFERENCE-ONLY ] FOR buffer-name [ , buffer-name ] ... ]
[ [ DATA-RELATION [ data-rel-name ] FOR data-rel-spec ] ]
```

**NEW SHARED DATASET dataset-name**

Defines and identifies a ProDataSet object that can be shared by one or more procedures called directly or indirectly by the current procedure. The ProDataSet object remains available to other procedures until the procedure that defined it ends. The called procedures must define the same ProDataSet object name as SHARED. For shared ProDataSet objects, each `buffer-name` must be the name of a shared buffer.

**Note:** Because a static SHARED TEMP-TABLE cannot have a BEFORE-TABLE, you cannot track changes on a static SHARED DATASET.

**SHARED DATASET dataset-name**

Defines and identifies a ProDataSet object that was initially defined by another procedure as NEW SHARED. For shared ProDataSet objects, each `buffer-name` must be the name of a shared buffer.

The procedure that initially defines the object determines the name. The procedures that share the object must define the object with the same name.

**PRIVATE | PROTECTED | STATIC DATASET dataset-name**

Defines and identifies a ProDataSet object as a data member of a class, and optionally specifies an access mode (PRIVATE or PROTECTED) and scope (instance or STATIC) for that data member. You cannot specify any of these options for a ProDataSet defined in an interface type definition (INTERFACE statement block) or when defining a ProDataSet as a data element of a procedure. For a data member ProDataSet, each `buffer-name` must be the name of a compatible data member buffer (see the FOR option).

**Note:** The specified options are applicable only when defining a data member for a class in a class definition (.cls) file. You cannot shadow (override) the definition of a given ProDataSet data member in a class hierarchy.

PRIVATE ProDataSet data members can be accessed only by the defining class.
PROTECTED ProDataSet data members can be accessed by the defining class and any of its derived classes. The default access mode is PRIVATE.

A ProDataSet defined with the STATIC option is a static data member of the class type for which it is defined, and it is scoped to the ABL session where it is referenced. ABL creates one copy of the specified class static ProDataSet on first reference to the class type, and ABL creates only one such copy for any number of instances of the class that you create. You cannot specify STATIC if you specify the REFERENCE-ONLY option. You
can directly reference an accessible static ProDataSet data member from any other static 
or instance class member defined in the same class or class hierarchy.

Without the STATIC option, ABL creates an instance ProDataSet data member that is 
sScoped to a single instance of the class where it is defined. ABL creates one copy of the 
specified instance ProDataSet for each such class instance that you create. You cannot 
directly reference an instance ProDataSet data member from a STATIC class member 
definition defined within the same class or class hierarchy.

For more information on accessing ProDataSets of different access modes and scopes, see 
the reference entry for Class-based data member access.

**Note:** Members of a class are grouped into six namespaces, including 
buffers/temp-tables, methods, variables/properties/events, ProDataSets, queries, 
and data-sources. ProDataSets defined as members of a class share the same 
namespace. There can be only one class member in this namespace with a given 
name.

For more information on where and how to define data members in a class, see the CLASS 
statement reference entry.

**DATASET** dataset-name

Defines and identifies a ProDataSet object in an interface, or for access only within the 
current external procedure or as a data member of the current class.

**NAMESPACE-URI** namespace

An optional CHARACTER constant that specifies the URI for the namespace of the 
ProDataSet object.

**NAMESPACE-PREFIX** prefix

An optional CHARACTER constant that specifies the namespace prefix associated with 
the NAMESPACE-URI.

**XML-NODE-NAME** node-name

An optional CHARACTER constant that specifies the name of the XML element 
representing the ProDataSet in an XML Document. The default is dataset-name. Use this 
option when the serialized name either contains invalid characters for an ABL name or the 
serialized name is an ABL keyword.

**Note:** If you set SERIALIZE-NAME but do not set XML-NODE-NAME, the AVM sets 
XML-NODE-NAME equal to SERIALIZE-NAME.

**SERIALIZE-NAME** serialize-name

An optional CHARACTER constant that specifies the name of the ProDataSet as it should 
appear when serialized, for example into JSON or XML. The default is dataset-name. Use this 
option when the serialized name either contains invalid characters for an ABL 
name or the serialized name is an ABL keyword.
REFERENCE-ONLY

Specifies that the procedure or class defining this ProDataSet object is using the object definition only as a reference to a ProDataSet object that is defined and instantiated in another procedure or class, and specified as a parameter in the invocation of a RUN statement, a method in a class, or a user-defined function, using either the BY-REFERENCE or BIND option. The AVM does not instantiate the reference-only object. You cannot specify REFERENCE-ONLY if you specify the STATIC option.

Passing a reference-only ProDataSet object parameter to a local routine, using either the BY-REFERENCE or BIND option allows the calling routine and the called routine to access the same object instance (instead of deep-copying the parameter).

Note: If you pass the parameter to a remote procedure, the AVM deep-copies the parameter on OUTPUT and the reference-only parameter is bound to that copy.

When you pass a ProDataSet parameter to a local routine using the BY-REFERENCE option, both the calling and called routines access the calling routine’s object instance (and ignore the called routine’s object instance). Since the called routine’s object instance is ignored, you should define the object as a reference-only object. When you define a reference-only ProDataSet object in the called routine and receive it from the calling routine using the BY-REFERENCE option, the AVM binds the definition of the object in the called routine to the object instance in the calling routine for the duration of the called routine. You cannot define a reference-only ProDataSet object in the calling routine and pass it to the called routine using the BY-REFERENCE option.

When you pass a ProDataSet parameter to a local routine using the BIND option, you can define a reference-only ProDataSet object in either the calling routine or the called routine as follows:

- When you define a reference-only ProDataSet object in the calling routine and pass it to the called routine using the BIND option, the AVM binds the calling routine to the object instance in the called routine. The reference-only object definition remains bound to the object instance until the routine containing the reference-only object definition is deleted or terminates. The parameter must be an OUTPUT parameter.

  Note: If you also define the ProDataSet object instance in the called routine as a reference-only object, you must bind the object in the called routine before returning to the calling routine.

- When you define a reference-only ProDataSet object in the called routine and receive it from the calling routine using the BIND option, the AVM binds the called routine to the object instance in the calling routine. The reference-only object definition remains bound to the object instance until the routine containing the reference-only object definition is deleted or terminates. The parameter must be an INPUT or INPUT-OUTPUT parameter.

In either case, you must specify the BIND option for the parameter in both the invocation of a RUN statement, a method in a class, or a user-defined function, and in the DEFINE PARAMETER statement.
**Caution:** Do not delete the object or routine to which a reference-only ProDataSet object is bound, or you might be left with references to an object that no longer exists.

When you define a ProDataSet object as reference-only, you must also define all member temp-tables as such. A temp-table object defined as reference-only can be a member of a reference-only ProDataSet object or a standard ProDataSet object. However, if you define a reference-only temp-table in a standard ProDataSet object, you cannot use the ProDataSet object until you bind the reference-only temp-table.

```FOR buffer-name [ , buffer-name ] ...```

Specifies the name of compile-time defined temp-table buffer that is scoped to the procedure or class in which the ProDataSet object is defined. For a shared ProDataSet, each `buffer-name` must be a shared buffer. If the ProDataSet is a data member of a class, you must specify the name of a compatible buffer data member. Thus, if the ProDataSet is a static data member, the buffer must also be a static data member; if the ProDataSet is PROTECTED, the buffer must also be defined as PROTECTED or inherited from a super class; and if the ProDataSet is PRIVATE, the buffer can be defined as either PRIVATE or PROTECTED. If the ProDataSet is a PRIVATE instance data member, you can also specify a default database table buffer; you cannot specify a default database buffer for a ProDataSet data member defined with any other combination of access mode and scope.

**Note:** ABL defines the default buffer for every database table that you access in a class as a PRIVATE instance buffer data member.

```DATA-RELATION [ data-rel-name ] FOR data-rel-spec```

Specifies a data-relation object.

The `data-rel-name` argument lets you name the data-relation object. You can use this name to obtain the object’s handle at run time. This argument is optional. The default name is `Relationn` (where `n` starts at 1 for each ProDataSet object).

The `data-rel-spec` argument specifies a pair of parent and child buffers for the data-relation object using the following syntax:

```
parent-buffer-name, child-buffer-name field-mapping-phrase
[ REPOSITION ] [ NESTED [ FOREIGN-KEY-HIDDEN ] ] [ NOT-ACTIVE ]
[ RECURSIVE ]
```

- `parent-buffer-name`
  - The parent buffer in the data-relation object. This must be one of the buffers identified by `buffer-name`.

- `child-buffer-name`
  - The child buffer in the data-relation object. This must be one of the buffers identified by `buffer-name`.  

**field-mapping-phrase**

Specifies the fields in the relation using the following syntax:

```plaintext
RELEVANT-FIELDS (parent-field1, child-field1
 [, parent-fieldn, child-fieldn ] ...)
```

The first field in the pair is from the parent buffer, the second field is from the child buffer. When filling the ProDataSet object, the AVM retrieves data for the child buffer based on an equality match between all pairs of fields unless the Data-Relation is deactivated or there is an explicit query definition for the data source of the child buffer.

You can define a query for the data source of the child buffer, or supply custom logic in response to FILL events that take over complete responsibility for filling one level of the ProDataSet object. In these cases, the `field-mapping-phrase` is not used.

When navigating the ProDataSet object, the AVM filters the data in the child buffer to include only children of the current parent.

**REPOSITION**

Specifies the relation mode as REPOSITION. The relation mode is SELECTION, by default.

When the relation mode is SELECTION, the ProDataSet object fills the child temp-table of the relation with all records related to the current parent. When the relation mode is REPOSITION, the relation is effectively ignored during a FILL, and the child of the relation is treated as if it were a top-level buffer.

When navigating a filled ProDataSet object with a SELECTION relation, related data is filtered as it is browsed. This means the child query of the relation is filtered to make available only children of the current parent, and the query is re-opened each time the parent table is repositioned. When navigating a filled ProDataSet object with a REPOSITION relation, the child table query is always set to match all the rows in the child table, and is not re-opened when the parent changes. Only the buffer for the child is repositioned to the matching child for the current parent.

A data-relation defined with REPOSITION or SELECTION is overridden if a query is defined for a child relation data-source. Normally, if REPOSITION is not specified, the child query selects the children of the parent. Coding a query for the child data-source overrides whether or not a SELECTION or REPOSITION relation mode was defined. By removing the query of the child data-source, the default child table load occurs.

**NESTED**

Specifies that child rows of a ProDataSet buffer are nested within their parent rows when writing a JSON representation of data or an XML representation of data or schema. This also causes the XML Schema definitions for the related temp-tables to be nested.
**DEFINE DATASET statement**

**Note:** If you do not nest child tables, the JSON string loses the data relation information. The serialization process also loses any information about key columns.

**FOREIGN-KEY-HIDDEN**

Specifies that foreign key fields in nested data relations are omitted when writing JSON or XML data, and that foreign key fields are optional in the XML Schema representation of the child table definition. This option can only be specified if the NESTED option is also specified.

When working with large ProDataSets, omitting foreign keys in nested child records can yield smaller JSON strings and XML documents, more efficient network transfers, and performance gains with the READ-*( ) and WRITE-*( ) methods.

Think carefully before deciding to use this feature. The READ-*( ) methods automatically populate foreign keys in nested child records with the value in the outer parent record when the foreign key is omitted from the serialized data. Unless you are sure that the data’s receiver will do the same, you should not specify FOREIGN-KEY-HIDDEN in your nested data-relations.

For example, while .NET can read this XML document and populate an ADO .NET Dataset, it will create rows in the child DataTable with a null value for the foreign key field. This is because it does not recognize the data-relation definition in the XML Schema as NESTED. ABL uses the prodata:_nested attribute in the XML Schema. .NET only recognizes its own msdata:IsNested attribute.

**NOT-ACTIVE**

Specifies that the data-relation is inactive. For example, this allows you to have two relations between the same two ProDataSet temp-table buffers, but only have one relation active at a time.

**RECURSIVE**

Instructs the ProDataSet FILL to load self-referencing elements, such as bill-of-materials parent/child tables or organization chart manager/employee tables. Support is provided for a recursive data-relation during a FILL for a ProDataSet or temp-table buffer. Navigation is not supported, but can be done normally through .NET, JAVA, or a recursive ABL procedure.

**Examples**

For examples of ProDataSet definitions and usage, see *OpenEdge Development: ProDataSets*.

For examples of instance and static ProDataSet data member definitions, see the descriptions of r-CustObj.cls, r-CustObjStatic.cls, and r-CustObjAbstract.cls in the CLASS statement reference entry.

**Notes**

- You cannot define a SHARED or NEW SHARED ProDataSet object in a class definition (.cls) file. If you do, ABL generates a compilation error.

- You cannot define a ProDataSet object within an internal procedure, a user-defined function, or a method of a class (including constructors, destructors, and property accessors).
- A ProDataSet can be compile-time defined (often referred to as a static ProDataSet object), where the ProDataSet is defined and created at compile time using this statement; or it can be run-time defined (often referred to as a dynamic ProDataSet object), where the ProDataSet is defined and created at run time using the CREATE DATASET statement and ProDataSet object handle operations. A compile-time defined ProDataSet can also be defined as a static data member of a class. In this case, it is a static ProDataSet object that is also a class static data member.

- A ProDataSet can have no more than one recursive data-relation.

See also: Buffer object handle, Class-based data member access, CREATE DATASET statement, Data-relation object handle, DEFINE QUERY statement, DEFINE TEMP-TABLE statement, GET-TOP-BUFFER() method, NUM-REFERENCES attribute, OPEN QUERY statement, ProDataSet object handle, RECURSIVE attribute

### DEFINE DATA-SOURCE statement

Defines a data-source object that is created at compile time for use in an external procedure or within a single class or class hierarchy.

**Syntax**

```
DEFINE [PRIVATE | PROTECTED] [STATIC] DATA-SOURCE data-source-name
FOR [QUERY query-name]
[ source-buffer-phrase , source-buffer-phrase ] ... ]
```

PRIVATE or PROTECTED data-source data members can be accessed only by the defining class. PROTECTED data-source data members can be accessed by the defining class and any of its derived classes. The default access mode is PRIVATE.

A data-source defined with the STATIC option is a static data member of the class type for which it is defined and is scoped to the ABL session where it is referenced. ABL creates one copy of the specified class static data-source on first reference to the class type, and ABL creates only one such copy for any number of instances of the class that you create. You can directly reference an accessible static data-source data member from any other static or instance class member defined in the same class or class hierarchy.

Without the STATIC option, ABL creates an instance data-source data member that is scoped to a single instance of the class where it is defined. ABL creates one copy of the
specified instance data-source for each such class instance that you create. You cannot directly reference an instance data-source data member from a STATIC class member definition defined within the same class or class hierarchy.

For more information on accessing data-sources of different access modes and scopes, see the reference entry for Class-based data member access.

**Note:** Members of a class are grouped into six namespaces, including buffers/temp-tables, methods, variables/properties/events, ProDataSets, queries, and data-sources. Data-sources defined as members of a class share the same namespace. There can be only one class member in this namespace with a given name.

For more information on where and how to define data members in a class, see the CLASS statement reference entry.

```plaintext
DATA-SOURCE data-source-name FOR

Defines and identifies a data-source object for access only within the current procedure, method of a class (including constructors, destructors, and property accessors), or as a PRIVATE data member of a class.

[ QUERY query-name ]

Specifies a query that defines the buffers for the data-source object. Use this option to override the default query for the data-source object.

You can also use the QUERY attribute to override the default query, or the FILL-WHERE-STRING attribute to override the WHERE clause in the query.

If the data-source is a data member of a class, you must specify the name of a compatible query. Thus, if the data-source is a static data member, the query must also be a static data member; if the data-source is PROTECTED, the query must also be defined as PROTECTED or inherited from a super class; and if the data-source is PRIVATE, the query can be defined as either PRIVATE or PROTECTED.

source-buffer-phrase [, source-buffer-phrase ] ...

Specifies one or more database or temp-table buffers for the data-source object using the following syntax:

```plaintext
buffer-name [ KEYS ( { field1 [, fieldn ]... | ROWID } ) ]
```

**buffer-name**

The name of the database or temp-table buffer. If the data-source is a data member of a class, you must define and specify the name of a compatible buffer data member for the table. Thus, if the data-source is a static data member, the buffer must also be a static data member; if the data-source is PROTECTED, the buffer must also be defined as PROTECTED or inherited from a super class; and if the data-source is PRIVATE, the buffer can be defined as either PRIVATE or PROTECTED. If the data-source is a PRIVATE instance data member, you can also specify a default
database table buffer; you cannot specify a default database buffer for a data-source data member defined with any other combination of access mode and scope.

**Note:** ABL defines the default buffer for every database table that you access in a class as a PRIVATE instance buffer data member.

**KEYS ( { field1 [ , fieldn ]... | ROWID } )**

Specifies one or more database table fields that constitute a unique key that can be used by the AVM to find a record in the table given a record in the temp-table that uses it as a data source.

The ROWID keyword can occur exactly once in place of a field list to use the ROWID as the key.

**Examples**

For examples of data-source definitions and usage, see *OpenEdge Development: ProDataSets*.

For examples of instance and static data-source data member definitions, see the descriptions of r-CustObj.cls, r-CustObjStatic.cls, and r-CustObjAbstract.cls in the CLASS statement reference entry.

**Note**

A data-source can be compile-time defined (often referred to as a `static` data-source object), where the data-source is defined and created at compile time using this statement, or it can be run-time defined (often referred to as a `dynamic` data-source object), where the data-source is defined and created at run time using the CREATE DATA-SOURCE statement and data-source object handle operations. A compile-time defined data-source can also be defined as a static data member of a class. In this case, it is a static data-source object that is also a class static data member.

---

**DEFINE EVENT statement**

Defines an ABL class event, declares a class event prototype in an ABL interface, or overrides an abstract class event inherited from an ABL or .NET abstract super class. A class event is a member of the class in which it is defined. You can publish a non-abstract event from within the defining class definition using the built-in Publish( ) event method in response to a condition that you determine. You can subscribe a class method or internal procedure as a handler for any accessible event (abstract or non-abstract) using the built-in Subscribe( ) event method. This handler executes whenever the event is published. You can also unsubscribe any handler using the built-in Unsubscribe( ) event method. The following description begins with general syntax for defining a class event.

**Note:** This statement is applicable only when used in a class or interface definition (.cls) file. For more information on class events, see the “Class Events Reference” section on page 1953.
## DEFINE EVENT statement

### Syntax

```
DEFINE [ PRIVATE | PROTECTED | PUBLIC ] [ STATIC | ABSTRACT ] [ OVERRIDE ]
EVENT event-name signature-spec
```

Use the following syntax to declare a class event prototype in an interface:

```
DEFINE [ PUBLIC ] EVENT event-name signature-spec
```

Use the following syntax to declare an abstract class event prototype:

```
DEFINE [ PROTECTED | PUBLIC ] [ OVERRIDE ] ABSTRACT
EVENT event-name signature-spec
```

[ PRIVATE | PROTECTED | PUBLIC ]

Specifies the access mode for this event. For a class event, the access mode indicates what code can call the `Subscribe()` event method on the event.

**Note:** You can only directly publish an event from within the class where it is defined, regardless of its access mode.

A PRIVATE event can have a handler subscribed to it only by the defining class. A PROTECTED event can have a handler subscribed to it by the defining class and any of its derived classes. A PUBLIC event can have a handler subscribed to it by:

- The defining class
- Any of its derived classes
- Any class or procedure that has access to a class instance that defines or inherits the event

Any piece of code can subscribe a handler to a PUBLIC static event. The default access mode is PUBLIC.

When declaring an interface event prototype, the access mode for the event must be PUBLIC (the default).

When defining an abstract event, the access mode for the event cannot be PRIVATE.

If this event is defined with the OVERRIDE option, the access mode cannot be more restrictive than the access mode defined for the overridden abstract ABL or .NET class event. ABL access modes correspond to the access levels of inherited .NET abstract events (in C#) as follows:

- PROTECTED matches either the .NET protected or protected internal access level.
- PUBLIC matches the .NET public access level.
[ STATIC ]

Defines an event that is a static member of the class type for which it is defined and that is scoped to the ABL session where it is referenced. ABL creates one copy of the specified class static event on first reference to the class type, and ABL creates only one such copy for any number of instances of the class that you create. You can subscribe a handler for an accessible static event in any piece of code. You can publish a static event only in an instance or static method that is defined within the same class definition where the static event is defined.

Without this option, ABL defines an instance event that is scoped to a single instance of the class where it is defined. ABL creates one copy of the specified instance event for each such class instance that you create. You can subscribe a handler for any public instance event (abstract or non-abstract) in any procedure, or in any instance or static method defined inside or outside of the class where the instance event is defined. Any static method can publish the public instance event only using an object reference to a class instance that defines the event as a member. If the referencing static method is defined in the same class as the public instance event, the class must instantiate itself in order to have access to an instance reference.

You can subscribe a handler for a private or protected instance event only in instance methods that are defined inside the same class or class hierarchy.

You can publish a non-abstract instance event only in a method that is defined within the same class definition where the instance event is defined. If the method is static, the instance event must also be public and you can only publish it using an object reference to an instance of the class. An instance method defined in the same class can also publish a public instance event using an object reference to an instance of the class.

**Note:** You cannot use a class instance that is not equal to the THIS-OBJECT system reference to subscribe a handler for a private or protected instance event, or to publish a private or protected instance event that is defined in the same class, because PRIVATE and PROTECTED access modes are instance based in ABL. Thus, private and protected instance members are accessible only to other members of the same class instance, where as public instance members can be accessed from other instances of the same class, including the session “static instance” of the class.

For more information on the mechanism for subscribing handlers to static and instance class events, see the Subscribe( ) event method reference entry. Note that the same constraints on subscribing handlers for static and instance class events applies to unsubscribing the handlers. For more information, see the Unsubscribe( ) event method. For more information on the mechanism for publishing instance and static class events, see the Publish( ) event method reference entry.

The STATIC option is not valid when you:

- Define or implement an abstract event
- Declare an interface event prototype
- Implement an interface event
DEFINE EVENT statement

[ ABSTRACT ]

Defines the event as an abstract instance member of the class type for which it is defined. The defining class type must also be abstract. If you define an abstract event, it has the following requirements:

- You must specify the OVERRIDE option if an inherited abstract event has the same name and signature.

**Note:** Class events cannot be overloaded. If you want to define an event with a different signature, it must also have a different name than any other event inherited by or defined in the same class.

- You can specify either a PROTECTED or a PUBLIC access mode, depending on any inherited abstract event you might be overriding.

- The abstract event must be overridden and implemented in a derived class.

Any class definition for an instance event that includes the OVERRIDE option and does not include the ABSTRACT option defines an event implementation. If it also includes the ABSTRACT option, the inherited abstract event remains abstract.

**Note:** You cannot publish an event that is defined as ABSTRACT.

This option is not valid either when you define a static event or when you declare an interface event prototype.

[ OVERRIDE ]

Specifies that this instance event overrides an abstract event inherited from an ABL or .NET class.

**Note:** A .NET abstract event or class is defined in C# with the abstract keyword.

When you specify OVERRIDE, event-name must be identical to the name of the overridden abstract event, and signature-spec must specify a signature that is identical to the signature defined for the overridden event. In addition, the access mode must not be more restrictive than the access mode defined for the overridden event. When overriding a .NET event, the signature-spec must specify the same delegate that is defined for the .NET event. For more information, see the description of the signature-spec option.

If you specify the ABSTRACT option, your overriding event is also defined as abstract, and it must be implemented in a class derived from the defining class. Note that you do not have to override an inherited abstract event that you want to remain abstract as long as the inheriting class is also abstract. However, doing so allows you to specify a less restrictive access mode for the abstract event.

If you do not specify the ABSTRACT option, your overriding event implements the inherited abstract event.

This option is not valid:
• When you define a static event
• When you declare an interface event prototype
• To override an inherited event that is implemented (not abstract)

**DEFINE EVENT statement**

EVENT event-name

Specifies the event name. This event name must be unique among all events, properties, and variable data members defined in the class hierarchy of the defining class, unless you specify the OVERRIDE option to override an inherited abstract event.

**Note:** Members of a class are grouped into six namespaces, including buffers/temp-tables, methods, variables/properties/events, ProDataSets, queries, and data-sources. Variables, properties, and events defined as members of a class share the same namespace. There can be only one class member in this namespace with a given name (not counting abstract member overrides).

**signature-spec**

Specifies the signature for the Publish() event method and for any class method or internal procedure that executes as a handler when the event is published. You can define this signature using one of the two options in the following syntax:

**Syntax**

```
{ [ SIGNATURE ] VOID ( [ parameter [ , parameter ] ... ] ) }
| [ DELEGATE ] [ CLASS ] dotNet-delegate-type }
```

```
[ SIGNATURE ] VOID ( [ parameter [ , parameter ] ... ] )
```

Defines an ABL method signature for the event, including the return value and zero or more parameters. The return value is always VOID. No associated internal procedure or method event handler can return a value. The SIGNATURE keyword is optional for readability.

If this event implements an ABL interface event or overrides an inherited ABL abstract event (using the OVERRIDE option), the interface or inherited abstract event must also be defined with an ABL method signature that matches this signature. If the ABL interface or inherited ABL abstract event is defined with a .NET signature (dotNet-delegate-type), you must use the .NET signature option to define this event instead.

For more information on the syntax of parameter and on matching parameters to implement or override ABL class events, see the Parameter definition syntax reference entry.

```
[ DELEGATE ] [ CLASS ] dotNet-delegate-type
```

Defines a .NET signature for the event as specified by a .NET delegate type (dotNet-delegate-type), for example, System.EventHandler. You can specify the delegate class name without a namespace (for example, EventHandler) with the presence of an appropriate USING statement. The DELEGATE or CLASS keyword is optional for readability. However the CLASS keyword, only, also disambiguates
a delegate type name that might be identical to an ABL primitive type name. Note
that ABL only supports .NET delegate types that conform to the .NET Framework
convention for event handlers. This convention defines an event handler signature
with a VOID return type and two input parameters, where the first parameter is a
System.Object and the second parameter is a System.EventArgs or a .NET class
derived from System.EventArgs. The .NET delegate type can also be a constructed
generic type. For more information on .NET generic types, see the Data types
reference entry.

You must use this option to define the ABL class event signature if the ABL event
implements a .NET interface event or overrides an inherited .NET abstract event
(using the OVERRIDE option). Also, the dotNet-delegate-type for the ABL event
must be identical to the .NET delegate type used to define the .NET interface or
abstract event.

You can use this option to define the signature for an ABL class event even if the
event does not implement or override a .NET event. However, if this event
implements an ABL interface event or overrides (using the OVERRIDE option) an
inherited ABL abstract event that is, itself, defined with a .NET delegate, you must
also define the signature for this event using an identical dotNet-delegate-type.

Note that you can identify the data types of .NET event parameters by looking up the
delegate type defined for the event in the appropriate .NET event documentation.

Examples

The following sample class and procedure files define, publish, subscribe an event handler to,
and unsubscribe an event handler from an ABL class event. The r-EventPublish sample class
defines the public NewCustomer event and a PubNewCustomer( ) method to publish it.

r-EventPublish.cls

```abl
CLASS r-EventPublish:
  /* Define an event */
  DEFINE PUBLIC EVENT NewCustomer
    SIGNATURE VOID ( INPUT pcCustName AS CHARACTER ).
  /* Code that publishes the event. */
  METHOD PUBLIC VOID PubNewCustomer( ):
    DEFINE VARIABLE cCustName AS CHARACTER INITIAL "A Customer Name" NO-UNDO.
    NewCustomer:Publish( INPUT cCustName ) NO-ERROR.
  END METHOD.
END CLASS.
```

The r-EventSubscribe sample class defines and subscribes a NewCustomer( ) method as a
handler for the event when it is instantiated, based on the object reference to the
r-EventPublish class that is passed to the constructor. Note that the event handler also
unsubscribes itself to the event after it executes.
The `r-EventPubSub.p` sample procedure instantiates these classes. The procedure then displays a frame that includes a `bNewCust` button that when clicked runs an internal procedure, which in turn invokes the `PubNewCustomer()` method on the `r-EventPublish` object to publish the event. This demonstrates how the class defining an event can allow a client class or procedure to publish it by providing a public method for the purpose. Note that any subsequent attempt to click the button does not run the event handler, because the handler has unsubscribed itself.

For more examples of class event definitions, including static and abstract events, see the descriptions of `r-CustObj.cls`, `r-CustObjStatic.cls`, and `r-CustObjAbstract.cls` in the `CLASS` statement reference entry.
DEFINE FRAME statement

Notes

- For information on using class event handlers and the built-in event methods, including Publish(), Subscribe(), and Unsubscribe(), and on .NET see the “Class Events Reference” section on page 1953.

- If you define an ABL event using a .NET delegate, .NET can only subscribe to this event if its definition implements or overrides an event defined in a .NET interface or abstract class.

See also

CLASS statement, INTERFACE statement, Parameter definition syntax, Publish() event method, Subscribe() event method, Type-name syntax, Unsubscribe() event method, USING statement

DEFINE FRAME statement

Defines and creates a frame or dialog box that is created at compile time for use in one or more procedures, or within a single class.

Syntax

```
DEFINE { [ [ NEW ] SHARED ] | [ PRIVATE ] } FRAME frame
     [ form-item ... ]
     [ { HEADER | BACKGROUND } head-item ... ]
     { [ frame-phrase ] }
```

```
DEFINE { [ [ NEW ] SHARED ] | [ PRIVATE ] } FRAME frame
     record [ EXCEPT field ... ]
     { [ frame-phrase ] }
```

NEW SHARED FRAME frame

Defines and identifies a frame to be shared by a procedure called directly or indirectly by the current procedure. The called procedure must name the same frame in a DEFINE SHARED FRAME statement.

SHARED FRAME frame

Defines and identifies a frame that was created by another procedure that used the DEFINE NEW SHARED FRAME statement. When you use the DEFINE SHARED FRAME statement, you cannot name any fields or variables in that frame that are not already named in the frame described by the DEFINE NEW SHARED FRAME statement.

[ PRIVATE ] FRAME frame

Defines and identifies a frame widget as a class-scoped object. A class-scoped handle-based object is not a member of a class, but provides a resource that is privately available to the class definition similar to a non-shared data element in a procedure definition. The option to specify the PRIVATE access mode is provided for readability. You cannot specify PRIVATE when defining a frame widget as a data element in a method or procedure.
Note: This option is applicable only when defining a class-scoped frame widget in a class
definition (.cls) file.

FRAME frame

Defines and identifies a frame widget for access only within the current procedure, class,
or method of a class.

form-item

Specifies a field-level widget or value to display in the frame, or a SPACE or SKIP
directive. The data specified by all form items is owned by a single field group, duplicated
for each data iteration in the frame.

This is the syntax for form-item:

```
{ 
  field [ format-phrase ]
  | constant [ at-phrase ]
  | { TO n } ]
  | BGCOLOR expression ]
  | DCOLOR expression ]
  | FGCOLOR expression ]
  | FONT expression ]
  | PFCOLOR expression ]
  | VIEW-AS TEXT ]
  | WIDGET-ID id-number ]
  | SPACE [ ( n ) ]
  | SKIP [ ( n ) ]
}
```

field

Specifies a field-level widget to be displayed in the frame. This value cannot be an
expression or a frame. To specify a child frame, you must first define the parent and
child frames, and then assign the FRAME attribute of the child frame to the handle
of the parent frame. The child frame is assigned to the same field group as other form
items.

format-phrase

Specifies one or more frame attributes for a field or variable. For more information
on format-phrase, see the Format phrase reference entry.

countant

A constant value.

at-phrase

Specifies the location of a value within the frame. The AT phrase does not left justify
the data; it simply indicates the placement of the data area. This is the syntax for
at-phrase:
DEFINE FRAME statement

AT \{ COLUMN column \ | COLUMN-OF reference-point \}
\{ ROW row \ | ROW-OF reference-point \}
[ COLON-ALIGNED \ | LEFT-ALIGNED \ | RIGHT-ALIGNED ]

AT \{ X x \ | X-OF reference-point \} \{ Y y \ | Y-OF reference-point \}
[ COLON-ALIGNED \ | LEFT-ALIGNED \ | RIGHT-ALIGNED ]

AT n

For more information, see the AT phrase reference entry.

TO n

The number (n) of the column where you want the right edge of the value. The TO option does not right justify the data; it simply indicates the placement of the data area.

BGCOLOR expression

Specifies the background color of the form item in graphical interfaces. This option is ignored in character interfaces.

DCOLOR expression

Specifies the display color of the form item in character interfaces. This option is ignored in graphical interfaces.

FGCOLOR expression

Specifies the foreground color of the form item in graphical interfaces. This option is ignored in character interfaces.

FONT expression

Specifies the font of the form item.

PFCOLOR expression

Specifies the prompt color of the form item in character interfaces. This option is ignored in graphical interfaces.

VIEW-AS TEXT

Specifies that the form item displays as a TEXT widget rather than as a FILL-IN.

WIDGET-ID id-number

Specifies a widget ID for a field-level widget or value to display in a frame. The value of id-number must be an expression that evaluates to an even integer value between 2 and 65534, inclusive, and must be unique across all widget IDs in the window or dialog box.
If you specify an invalid ID, the compiler displays an error message. This option is supported in graphical interfaces only, and only in Windows.

**SPACE ( n )**

Identifies the number (n) of blank spaces to insert after the expression displays. The n can be 0. If the number of spaces you specify is more than the spaces left on the current line of the frame, the AVM starts a new line and discards extra spaces. If you do not use this option or you do not use n, the AVM inserts one space between items in the frame.

**SKIP ( n )**

Identifies the number (n) of blank lines to insert after the expression is displayed. The number of blank lines can be 0. If you do not use this option, the AVM does not skip a line between expressions unless the expressions do not fit on one line. If you use the SKIP option but do not specify n, or if n is 0, the AVM starts a new line unless it is already at the beginning of a new line.

**record**

Represents the name of the record you want to display. Naming a record is shorthand for listing each field individually, as a form item.

**EXCEPT field . . .**

Tells the AVM to display all the fields in the frame except those fields listed in the EXCEPT phrase.

**HEADER**

Tells the AVM to place the following items in a header section at the top of the frame in a separate field group from all other data. In addition to fields, variables, and constants, the frame header can contain expressions, images, and rectangles. The AVM reevaluates these expressions each time it displays the frame.

When you use the HEADER option, the AVM disregards OpenEdge Data Dictionary field labels for fields you name in the DEFINE FRAME statement. Use character strings to specify labels on fields you name in the frame header.

**BACKGROUND**

Specifies that any following frame items are displayed in the frame background, behind the data and header in a separate field group. Typically, this option is used to display images or rectangles behind the data.

**head-item**

A description of a value displayed in the frame header or background, or a SPACE or SKIP directive. Following is the syntax for head-item:
This is exactly the same as the syntax for a form-item, except that a head-item can be an expression and does not include the PFCOLOR option. If you use an expression in a HEADER or BACKGROUND phrase, the expression is evaluated each time the frame is viewed. If you give the PAGE-TOP or PAGE-BOTTOM option for the frame, the expression is evaluated for each page. This lets you include a reference to the PAGE-NUMBER function in the frame header.

frame-phrase

Specifies additional options for the frame, including the VIEW-AS DIALOG-BOX option to define the frame as a dialog box. For more information on frame and dialog box options, see the Frame phrase reference entry.

Examples

The following example, r-deffrm.p, uses the DEFINE FRAME statement to set up the format of a frame. It then scopes that frame to a FOR EACH block.

r-deffrm.p

DEFINE VARIABLE bal-avail NO-UNDO LIKE Customer.Balance
COLUMN-LABEL "Available!Credit" NO-UNDO.

DEFINE FRAME cust-bal
   Customer.CustNum
   Customer.Name FORMAT "X(20)"
   Customer.CreditLimit LABEL "Limit"
   Customer.Balance
   bal-avail
   WITH CENTERED ROW 3 TITLE "Available Customer Credit" USE-TEXT.

FOR EACH Customer NO-LOCK WITH FRAME cust-bal:
   DISPLAY
      Customer.CustNum
      Customer.Name
      Customer.CreditLimit
      Customer.Balance
      Customer.CreditLimit - Customer.Balance @ bal-avail.
END.

The following example defines three frames. The cust-info frame is scoped to the trigger for the b_next button where it is first referenced. Similarly, the cust-dtl frame is scoped to the b_dt1 trigger. The butt-frame frame is scoped to the outer procedure block.
The following example uses a set of thin rectangles as lines to create graphic columns within a frame background:
The following procedure defines the shared frame cust-frame. It also defines a shared variable and a shared buffer. For each Customer whose Customer number is less than 20, the procedure displays Customer information in the cust-frame. The format for the cust-frame is defined in the r-shrfrm.i include file.

The following procedure defines the shared frame cust-frame. It also defines a shared variable and a shared buffer. For each Customer whose Customer number is less than 20, the procedure displays Customer information in the cust-frame. The format for the cust-frame is defined in the r-shrfrm.i include file.

Following is the r-shrfrm.i include file:
After the `r-shrfrm.p` procedure displays the Customer information, it calls the `r-updord.p` procedure.

The `r-updord.p` procedure defines the variable, frame, and buffer that were originally defined in the `r-shrfrm.p` procedure. However, in this second reference to the items, the keyword NEW is omitted. The `r-updord.p` procedure displays, and lets you update, the Order information for the Customer displayed in the cust-frame. The Order information is displayed in the same frame.

### `r-shrfrm.i`

```plaintext
FORM
  xcust.Name COLON 10
  xcust.Phone COLON 55
  xcust.Address COLON 1
  xcust.SalesRep COLON 55
  csz NO-LABEL COLON 10
  xcust.CreditLimit COLON 55 SKIP(2)
  Order.OrderNum COLON 10 Order.OrderDate COLON 30
  Order.ShipDate COLON 30
  Order.PromiseDate COLON 30
  WITH SIDE-LABELS 1 DOWN CENTERED ROW 5
  TITLE "Customer/Order Form" FRAME cust-frame.
```

The following example, `r-fof1.p`, creates a dialog box to display Customer information from a query. The dialog box contains three child frames to display Customer contact information (FRAME cont-fr), Customer account information (FRAME acct-fr), and control buttons for moving through the query results list (FRAME ctrl-fr).

### `r-updord.p`

```plaintext
DEFINE SHARED FRAME cust-frame.
DEFINE SHARED VARIABLE csz AS CHARACTER NO-UNDO FORMAT "x(29)".
DEFINE SHARED BUFFER xcust FOR Customer.

FOR EACH Order OF xcust:
  {r-shrfrm.i} /* shared frame layout */
  DISPLAY Order.OrderNum WITH FRAME cust-frame.
  UPDATE Order.OrderDate Order.ShipDate Order.PromiseDate
     WITH FRAME cust-frame.
END.
```

The following example, `r-fof1.p`, creates a dialog box to display Customer information from a query. The dialog box contains three child frames to display Customer contact information (FRAME cont-fr), Customer account information (FRAME acct-fr), and control buttons for moving through the query results list (FRAME ctrl-fr).
DEFINE FRAME cust-fr SKIP(.5)
  Customer.Comments AT COLUMN 6 ROW 13.5
  WITH SIDE-LABELS TITLE "Customer Data" SIZE 80 BY 15 VIEW-AS DIALOG-BOX.
DEFINE FRAME cont-fr SKIP(.5)
  Customer.Address COLON 17 SKIP
  Customer.Address2 COLON 17 SKIP
  Customer.City COLON 17 SKIP
  Customer.State COLON 17 SKIP
  Customer.ZipCode COLON 17 SKIP
  Customer.Country COLON 17 SKIP
  Customer.Contact COLON 17 SKIP
  Customer.Phone COLON 17
  WITH SIDE-LABELS TITLE "Contact Information" SIZE 40 BY 10 AT COLUMN 1 ROW 3.
DEFINE FRAME acct-fr SKIP(.5)
  Customer.Balance COLON 15 SKIP
  Customer.CreditLimit COLON 15 SKIP
  Customer.Discount COLON 15 SKIP
  Customer.Terms COLON 15
  WITH SIDE-LABELS TITLE "Account Information" SIZE 38.85 BY 6 AT COLUMN 41 ROW 3.

ON CHOOSE OF bnext DO:
  GET NEXT custq.
  IF NOT AVAILABLE Customer THEN GET FIRST custq.
  RUN display-proc IN THIS-PROCEDURE.
END.

ON CHOOSE OF bprev DO:
  GET PREV custq.
  IF NOT AVAILABLE Customer THEN GET LAST custq.
  RUN display-proc IN THIS-PROCEDURE.
END.

FRAME cont-fr:FRAME = FRAME cust-fr:HANDLE.
FRAME acct-fr:FRAME = FRAME cust-fr:HANDLE.
FRAME ctrl-fr:FRAME = FRAME cust-fr:HANDLE.

OPEN QUERY custq PRESELECT EACH Customer BY Customer.Name.
GET FIRST custq.
RUN display-proc IN THIS-PROCEDURE.
ENABLE ALL WITH FRAME ctrl-fr.

WAIT-FOR WINDOW-CLOSE OF FRAME cust-fr.

PROCEDURE display-proc:
  DISPLAY
    Customer.Name Customer.CustNum Customer.SalesRep
    Customer.Comments WITH FRAME cust-fr.
  DISPLAY
    WITH FRAME cont-fr.
  DISPLAY
    WITH FRAME acct-fr.
END PROCEDURE.
You cannot define a SHARED or NEW SHARED frame widget in a persistent procedure. If you do, ABL raises ERROR on the RUN statement that creates the procedure.

You cannot define a SHARED or NEW SHARED frame widget in a class definition (.cls) file. If you do, ABL generates a compilation error.

If you do not specify the font for a frame, ABL uses the system default font, not the font of the window. This is because ABL determines the frame layout at compile time when the window’s fonts (known at run time) are not yet available.

You can use just one DEFINE FRAME statement per frame in a procedure.

If you name variables or parent child frames to a shared frame, ABL does not automatically make those variables and child frames shared. If you want to share the variables and child frames among procedures, you must define each variable and frame using the SHARED option in all the sharing procedures.

ABL scopes a newly defined frame to the block that first references the frame. (The DEFINE FRAME statement does not count as a reference.) ABL scopes a shared frame outside of the called procedure.

The frame-phrase options specified in a DEFINE NEW SHARED FRAME statement are carried over to all corresponding DEFINE SHARED FRAME statements and cannot be overridden.

You can use different field-level help and validation in new shared, and shared frames.

You must define a shared frame before referencing that frame in a procedure.

All frame fields and Frame phrase options in a shared frame must first be defined in the initial DEFINE NEW SHARED FRAME statement or an additional FORM statement in the same procedure. Procedures that share this frame only have to define fields that correspond to the fields in the initial definition plus any specified ACCUM option. Other Frame phrase options for the SHARED frames are allowed, but are ignored except for the ACCUM option. This allows you to make use of the same FORM statement in an include file for both the NEW SHARED and matching SHARED frames. See the FORM statement reference entry for more information.

If you use an Aggregate phrase to accumulate a value within a shared frame, you must also use the ACCUM option in each procedure that uses the shared frame.

If you define a frame to use as a DDE frame, you must realize the frame (display it) before using it as a conversation end-point. If you want the DDE frame to remain invisible during its use in a DDE conversation, set its HIDDEN attribute to TRUE after realizing the frame. For information on DDE frames, see OpenEdge Development: Programming Interfaces.

If you have enabled application-defined widget IDs in your ABL GUI application, by specifying the Use Widget ID (–usewidgeid) startup parameter, then the AVM uses the value specified in the WIDGET-ID option to set the WIDGET-ID attribute for this widget when it creates the widget at run time, instead of using the widget ID it normally generates by default. If you have not enabled application-defined widget IDs, then the AVM ignores this option setting at run time.

For more information about the WIDGET-ID attribute, see its reference entry in the “Handle Attributes and Methods Reference” section on page 1271. For more information
DEFINE IMAGE statement

about the Use Widget ID (-usewidgetid) startup parameter, see OpenEdge Deployment: Startup Command and Parameter Reference.

See also Class-based data member access, DEFINE BUFFER statement, DEFINE VARIABLE statement, FORM statement, Frame phrase, RUN statement

DEFINE IMAGE statement
(Windows only; Graphical interfaces only)

Defines an image widget in a graphical interface that is created at compile time for use within a single procedure or class. An image widget is a container for an operating system image file and can be displayed in a form or used as a form background.

Note: Does not apply to SpeedScript programming.

Syntax

```plaintext
DEFINE [ PRIVATE ] IMAGE image-name
   { image-phrase | LIKE image | size-phrase }
   [ BGCOLOR expression ]
   [ FGCOLOR expression ]
   [ CONVERT-3D-COLORS ]
   [ TOOLTip tooltip ]
   [ STRETCH-TO-FIT [ RETAIN-SHAPE ] ] [ TRANSPARENT ]
```

[ PRIVATE ] IMAGE image-name

Defines and identifies an image widget as a class-scoped object. A class-scoped handle-based object is not a member of a class, but provides a resource that is privately available to the class definition similar to a non-shared data element in a procedure definition. The option to specify the PRIVATE access mode is provided for readability. You cannot specify PRIVATE when defining an image widget as a data element in a method or procedure.

Note: This option is applicable only when defining a class-scoped image widget in a class definition (.cls) file.

IMAGE image-name

Defines and identifies an image widget for access only within the current procedure, class, or method of a class.

image-phrase

Specifies the file where the image is stored and the portion of the image to read. This is the syntax for image-phrase:
DEFINE IMAGE statement

For more information on this syntax, see the Image phrase reference entry.

You must specify either the LIKE option, an Image phrase or a Size phrase within the DEFINE IMAGE statement, and you may specify any two or all three.

LIKE image

Specifies a previously defined image from which this image inherits attributes. You can override specific attributes by specifying other options of the DEFINE IMAGE statement.

You must specify either the LIKE option, an Image phrase or a Size phrase within the DEFINE IMAGE statement, and you may specify any two or all three.

size-phrase

Specifies the outside dimensions of the image widget. This is the syntax for size-phrase:

```plaintext
{ SIZE | SIZE-CHARS | SIZE-PIXELS } width BY height
```

If you specify SIZE or SIZE-CHARS, the units are characters; if you specify SIZE-PIXELS, the units are pixels. If you use character units, the values width and height must be decimal constants; for pixel units, they must be integer constants. For more information, see the SIZE phrase reference entry.

You must specify either the LIKE option, an Image phrase or a Size phrase within the DEFINE IMAGE statement, and you may specify any two or all three.

BGCOLOR expression

Has no effect; supported only for backward compatibility.

FGCOLOR expression

Has no effect; supported only for backward compatibility.

CONVERT-3D-COLORS

Specifies that the colors associated with an image will be converted to the system 3D colors when an image is loaded. Table 29 describes the color conversion process.
During a session, if Windows notifies the AVM that the system colors are changed, all images that have this option are reloaded and converted to the new system colors.

**TOOLTIP tooltip**

Allows you to define a help text message for an image widget. The AVM automatically displays this text when the user pauses the mouse pointer over the image widget.

You can add or change the TOOLTIP option at any time. If TOOLTIP is set to "" or the Unknown value (?), then the ToolTip is removed from the button. No ToolTip is the default. ToolTips are supported in Windows only.

**STRETCH-TO-FIT**

Forces the image to expand or contract to fit within the image widget’s boundaries.

This option has no effect if an icon is displayed on the image widget.

**RETAIN-SHAPE**

Indicates that the image should retain its aspect ratio (expand or contract equally in both dimensions). This may leave some uncovered space at the bottom or right of the image widget.

RETAIN-SHAPE is ignored if STRETCH-TO-FIT is FALSE or if an icon is displayed on the image widget.

**TRANSPARENT**

Indicates that the background color of the image is transparent. The background color is determined by the color of the pixel in the lower left corner of the image.

The TRANSPARENT option overrides the CONVERT-3D-COLORS option; if both are set, CONVERT-3D-COLORS is ignored.

This option has no effect if an icon is displayed on the image widget.

**Example**

This procedure defines an image widget named trashcan, and loads into the widget a series of operating system image files that create an animation of a fire burning in a trash can. The user begins the animation by choosing the Animate button. This procedure serves as an illustration only. It depends on the existence of image filenames ANI01, ANI02, ... ANI14, which are not provided.
DEFINE MENU statement

Defines a menu widget that is created at compile time for use in one or more procedures, or within a single class. You can use a menu widget as a pop-up menu or a menu bar.

**Note:** Does not apply to SpeedScript programming.

---

**r-image.p**

```plaintext
DEFINE VARIABLE repeat_loop AS INTEGER NO-UNDO.
DEFINE VARIABLE animation_loop AS INTEGER NO-UNDO.
DEFINE VARIABLE lok AS LOGICAL NO-UNDO.

DEFINE BUTTON animate LABEL "Animate".
DEFINE IMAGE trashcan FILE "ANI01.BMP".

DISPLAY animate trashcan WITH FRAME y TITLE "** Animation Sample **".

ON CHOOSE OF animate IN FRAME y DO:
/* Begin Animation */
DO repeat_loop = 1 TO 5:
   DO animation_loop = 1 TO 14:
      lok = trashcan:LOAD-IMAGE("ANI" + STRING(animation_loop,"99")) IN FRAME y.
   END.
END.
END.
UPDATE animate WITH FRAME y.
```

---

**Notes**

- In Windows, if the file has no extension, the AVM by default looks for image files with either a .bmp or .ico extension.

- To create the compile-time defined image you are defining, you must define a compile-time defined frame that contains the image. Each frame you define that contains the same image creates an additional instance of that image. The handle for a compile-time defined image is not available until the image is created.

- The AVM only performs the color conversion process on bitmaps (.bmp files) that contain 256 or fewer colors. However, you might consider using 16-color bitmaps because only the first sixteen entries in the bitmap’s color table will be converted.

- Icon colors (.ico files) are not converted, even if CONVERT-3D-COLORS is TRUE.

- See Image phrase for the list of supported image file formats.

- You can specify an application-defined widget ID for a compile-time defined image using the `form-item` phrase in either the FORM statement or the DEFINE FRAME statement. See the FORM statement and DEFINE FRAME statement reference entries for more information.

Class-based data member access, FORM statement, Image phrase
DEFINE MENU statement

Syntax

```
DEFINE { [ [ NEW ] SHARED ] | [ PRIVATE ] } MENU menu-name

[ FGCOLOR expression ]
[ BGCOLOR expression ]
[ DCOLOR expression ]
[ PFCOLOR expression ]
[ FONT number ]
[ { TITLE title } | MENUBAR ]
[ { LIKE menu } | menu-element-descriptor ... ]
```

NEW SHARED MENU menu-name

Defines and identifies a menu widget that can be used by other procedures. The menu remains available to other procedures until the procedure that contains this statement ends.

SHARED MENU menu-name

Defines and identifies a menu widget that was created in another procedure with the DEFINE NEW SHARED MENU statement.

PRIVATE] MENU menu-name

Defines and identifies a menu widget as a class-scoped object. A class-scoped handle-based object is not a member of a class, but provides a resource that is privately available to the class definition similar to a non-shared data element in a procedure definition. The option to specify the PRIVATE access mode is provided for readability. You cannot specify PRIVATE when defining a menu widget as a data element in a method or procedure.

**Note:** This option is applicable only when defining a class-scoped menu widget in a class definition (.cls) file.

MENU menu-name

Defines and identifies a menu widget for access only within the current procedure, class, or method of a class.

BGCOLOR expression

Supported only for backward compatibility.

DCOLOR expression

Specifies the display color for the menu in character interfaces. This option is ignored in graphical interfaces.

FGCOLOR expression

Supported only for backward compatibility.

PFCOLOR expression

Specifies the prompt-for color for the menu in character interfaces. This option is ignored in graphical interfaces.
DEFINE MENU statement

FONT number

Supported only for backward compatibility.

MENUBAR

Specifies that the menu displays as a menu bar.

TITLE title

Specifies the title of the menu. Only pop-up menus can have titles. This option is invalid for menu bars. The title displays at the top of the menu. In environments that do not support this option, it is ignored.

LIKE menu

Specifies a previously defined menu whose characteristics you want to apply to the new menu. If you name a menu with this option, you must have defined that menu previously in the procedure.

menu-element-descriptor

Specifies an element display on the menu. Each element is either a normal menu item, a submenu, a rule, or a blank space. The last two are valid only for pop-up menus. You must specify one or more menu elements, unless you use the LIKE option.

This is the syntax for menu-element-descriptor:

```plaintext
{ menu-item-phrase
    SUB-MENU submenu [ DISABLED ] [ LABEL label ]
    RULE
    SKIP
}
```

RULE

Specifies that a rule or line is inserted at this point in the menu. You can use this, for example, to divide the menu into sections.

SKIP

Specifies that a blank line is inserted at this point in the menu. You can use this, for example, to divide the menu into sections.

SUB-MENU submenu [ DISABLED ] [ LABEL label ]

Specifies that a submenu displays as a menu item. The submenu must be previously defined in the procedure. The submenu appears when the user chooses that item. The submenu cannot be a menu bar. The DISABLED and LABEL options for a submenu are the same as described for the menu-item-phrase.

menu-item-phrase

Specifies a normal menu item. This is the syntax for menu-item-phrase:
DEFINE MENU statement

MENU-ITEM  menu-item-name
  [ ACCELERATOR  keylabel ]
  [ BGCOLOR  expression ]
  [ DCOLOR  expression ]
  [ DISABLED ]
  [ FGCOLOR  expression ]
  [ FONT  expression ]
  [ LABEL  label ]
  [ PFCOLOR  expression ]
  [ READ-ONLY ]
  [ TOGGLE-BOX ]
  [ trigger-phrase ]

MENU-ITEM  menu-item-name

The name of the menu item you are defining.

ACCELERATOR  keylabel

Specifies a keyboard accelerator for this menu item. A keyboard accelerator is a key—sometimes modified by SHIFT, CONTROL, or ALT—that chooses a menu item even if the menu is not displayed. The value keylabel must be character-string expression that evaluates to a valid key label recognized by the AVM, such as a, F1, or ALT+SHIFT+F1. See the chapter on handling user input in the OpenEdge Development: Programming Interfaces for the precedence rules that the AVM uses for handling keyboard input.

BGCOLOR  expression

Specifies the background color for the menu item in graphical environments. If you omit this option, the menu item inherits the background color of the menu.

DCOLOR  expression

Specifies the display color for the menu item in character interfaces. If you omit this option, the menu item inherits the display color of the menu.

DISABLED

Specifies that the menu item is initially disabled for input. This means that the user cannot choose this item. Disabled items are grayed out (in environments that support it).

FGCOLOR  expression

Specifies the foreground color for the menu item in graphical environments. If you omit this option, the menu item inherits the foreground color of the menu.

FONT  expression

Specifies the font for the menu item. If you omit this option, the menu item inherits the font of the menu.

LABEL  label

Specifies the text that is displayed in the menu for a choosable menu item or submenu. Include an ampersand (&) within the label to assign the following letter as a mnemonic for
the menu item. This means that when the menu is displayed, the user can choose the item by pressing that single key. If you do not include an ampersand within the label, Windows treats the first character as a mnemonic.

To include a literal ampersand within a label, specify two ampersands (&&).

**PFCOLOR expression**

Specifies the prompt-for color for the menu item in character interfaces. If you omit this option, the menu item inherits the prompt-for color of the menu.

**READ-ONLY**

Specifies that this menu item is read-only text. The user cannot choose this item.

**TOGGLE-BOX**

Specifies that the menu item is displayed as a checkbox that the user can toggle on or off. In environments that do not support this option, it is ignored.

**trigger-phrase**

Specifies application triggers for the menu item. Typically, you associate a CHOOSE trigger with each menu item.

For more information, see the *Trigger phrase* reference entry.

**Example**

The `r-bar.p` procedure defines a menu bar, mbar, that contains three pull-down submenus labeled Topic, Move, and Exit. The handle of mbar is assigned to the current window. The ON statements define triggers to execute when you choose the corresponding menu items.
DEFINE SUB-MENU topic
  MENU-ITEM numbr LABEL "Cust. Number"
  MENU-ITEM addr LABEL "Address"
  MENU-ITEM othrinfo LABEL "Other".
DEFINE SUB-MENU move
  MENU-ITEM forward LABEL "NextRec" ACCELERATOR "PAGE-DOWN"
  MENU-ITEM backward LABEL "PrevRec" ACCELERATOR "PAGE-UP".
DEFINE SUB-MENU quitit
  MENU-ITEM quititem LABEL "E&xit".

DEFINE MENU mbar MENUBAR
  SUB-MENU topic LABEL "Topic"
  SUB-MENU move LABEL "Move"
  SUB-MENU quitit LABEL "E&xit".

ON CHOOSE OF MENU-ITEM numbr
  DISPLAY Customer.CustNum.

ON CHOOSE OF MENU-ITEM addr
  DISPLAY Customer.Address Customer.Address2 Customer.City
  Customer.State Customer.PostalCode
  WITH FRAME addr-frame NO-LABLES COLUMN 25.

ON CHOOSE OF MENU-ITEM othrinfo
  DISPLAY Customer EXCEPT Customer.Name Customer.CustNum Customer.Address
  WITH FRAME oth-frame SIDE-LABLES.

ON CHOOSE OF MENU-ITEM forward DO:
  HIDE ALL NO-PAUSE.
  CLEAR FRAME name-frame.
  FIND NEXT Customer NO-ERROR.
  IF AVAILABLE Customer THEN
    DISPLAY Customer.Name WITH FRAME name-frame.
  END.
END.

ON CHOOSE OF MENU-ITEM backward DO:
  HIDE ALL NO-PAUSE.
  CLEAR FRAME name-frame.
  FIND PREV Customer NO-ERROR.
  IF AVAILABLE Customer THEN
    DISPLAY Customer.Name WITH FRAME name-frame.
  END.
END.

FIND FIRST Customer.
DISPLAY Customer.Name LABEL "Customer Name" WITH FRAME name-frame.
ASSIGN CURRENT-WINDOW:MENUBAR = MENU mbar:HANDLE.
WAIT-FOR CHOOSE OF MENU-ITEM quititem.

Notes

• You cannot define a SHARED or NEW SHARED menu widget in a persistent procedure.
  If you do, ABL raises ERROR on the RUN statement that creates the procedure.

• You cannot define a SHARED or NEW SHARED menu widget in a class definition (.c1s) file.
  If you do, ABL generates a compilation error.

• Keyboard accelerators are specified for menu-items forward and backward. The user can
  press PAGE-DOWN key to look at the next Customer record and the PAGE-UP to view
  the previous Customer record.

• The menu item quititem has a label E&xit; the ampersand makes X the mnemonic for that
  menu item.
• You cannot define a submenu with the same name more than once in the same menu tree. Thus, if menu mFile contains both submenu mOptions and submenu mSave, submenu mSave cannot also contain submenu mOptions.

• Menu items in different menus and submenus can have the same names. In the above procedure, the menu items in myfile and myobjects share the same names. To avoid ambiguity, use the IN MENU or IN SUB-MENU option to identify the parent menu or submenu.

• There are instances where you cannot avoid ambiguity in menu item references. In such instances, ABL always references the first unambiguous instance of the menu item. In particular, if the same submenu containing a menu item appears in more than one menu and each menu defines another instance of the same menu item, you can only reference that menu item in the submenu from the first menu that contains it. Thus, if submenu mOptions contains menu item mSave and the menus mFile and mDraw (in that order) both contain submenu mOptions and another menu item mSave, you can only reference menu item mSave in submenu mOptions from menu mFile. You cannot uniquely reference menu item mSave in submenu mOptions from menu mDraw because menu mDraw contains another menu item mSave.

See also  
Class-based data member access, COLOR phrase, DEFINE SUB-MENU statement, RUN statement

DEFINE PARAMETER statement

Defines a run-time parameter in an ABL procedure (internal or external), Windows dynamic link library (DLL) routine, UNIX shared library routine, or ActiveX control event procedure.

Note: To define run-time parameters of a user-defined function, or a method within a class (including constructors), see the Parameter definition syntax reference entry.

Each parameter requires its own DEFINE statement. The parameters must be specified in the RUN statement in the same order they are defined with DEFINE statements. In addition, the parameter types (INPUT, OUTPUT, INPUT-OUTPUT, RETURN, TABLE, TABLE-HANDLE, DATASET, DATASET-HANDLE, and BUFFER) specified in the DEFINE and RUN statements must agree. The corresponding data types and run-time values must also be compatible enough to allow the AVM to perform any necessary conversions.
DEFINE PARAMETER statement

Syntax

```
DEFINE { INPUT | OUTPUT | INPUT-OUTPUT | RETURN } PARAMETER parameter
{ { AS [ HANDLE TO ] primitive-type-name
| AS [ CLASS ] { object-type-name }
| LIKE field } } [ EXTENT [ constant ] ]
[ [ NOT ] CASE-SENSITIVE ]
[ FORMAT string ]
[ DECIMALS n ]
[ INITIAL
   { constant | { constant [ , constant ] ... } } ]
[ COLUMN-LABEL label ]
[ LABEL string ]
[ NO-UNDO ]
```

```
DEFINE PARAMETER BUFFER buffer-name FOR [ TEMP-TABLE ] table-name
[ PRESELECT ]
```

```
DEFINE { INPUT | OUTPUT | INPUT-OUTPUT } PARAMETER
{ TABLE FOR temp-table-name [ APPEND ] [ BIND ] [ BY-VALUE ]
| TABLE-HANDLE temp-table-handle [ BIND ] [ BY-VALUE ]
| DATASET FOR dataset-name [ APPEND ] [ BIND ] [ BY-VALUE ]
| DATASET-HANDLE dataset-handle [ BIND ] [ BY-VALUE ]
}
```

**INPUT PARAMETER**

Defines a parameter that gets its value from one of the following sources:

- If the calling procedure runs the current (called) procedure synchronously, the value comes from the corresponding INPUT parameter of the RUN statement.
- If the current procedure is the event procedure specified to handle the PROCEDURE-COMPLETION event for an asynchronous remote procedure, the value comes from the corresponding OUTPUT or INPUT-OUTPUT parameter of the remote procedure.

**OUTPUT PARAMETER**

Defines a parameter that returns a value to one of the following destinations:

- If the calling procedure runs the current (called) procedure synchronously, the value is returned to the corresponding OUTPUT parameter of the RUN statement in the calling procedure.
- If the calling procedure runs the current (called) procedure as an asynchronous remote procedure, the value is returned to the corresponding INPUT parameter of the event procedure specified to handle the PROCEDURE COMPLETE event for the current procedure.
INPUT-OUTPUT PARAMETER

Defines a parameter that receives an initial value passed from the calling procedure that can be subsequently modified by the called procedure. The calling procedure cannot pass a literal value. The called procedure returns the modified value to one of the following destinations:

- If the calling procedure runs the current (called) procedure synchronously, the value is returned to the corresponding INPUT-OUTPUT parameter of the RUN statement in the calling procedure.
- If the calling procedure runs the current (called) procedure as an asynchronous remote procedure, the value is returned to the corresponding INPUT parameter of the event procedure specified to handle the PROCEDURE COMPLETE event for the current procedure.

RETURN PARAMETER

Defines a parameter that holds the return value of a DLL or UNIX shared library routine. When the DLL routine returns, the value of this parameter is passed back to the calling procedure. You can only have one RETURN parameter per routine.

**parameter**

Identifies the name of the parameter you want to define.

**AS [ HANDLE TO ] primitive-type-name**

Specifies a primitive type for the parameter.

For ABL procedures, *primitive-type-name* can specify any built-in primitive type used to define variables. For more information on the available primitive types, see the Data types reference entry. For more information on defining primitive type variables, see the DEFINE VARIABLE statement reference entry.

For DLL or UNIX shared library routines, *primitive-type-name* can specify an ABL DLL data type. ABL DLL data types include the built-in ABL data types CHARACTER and MEMPTR, Windows DLL-equivalent data types, and UNIX shared library data types.

Table 30 shows how Windows DLL and UNIX shared library data types map to ABL DLL data types.

**Table 30: Data types for DLL and UNIX shared library routine parameters (1 of 2)**

<table>
<thead>
<tr>
<th>Example C data type</th>
<th>ABL DLL parameter data type</th>
<th>Windows DLL and UNIX shared library data type</th>
</tr>
</thead>
<tbody>
<tr>
<td>char</td>
<td>BYTE</td>
<td>8-bit unsigned integer</td>
</tr>
<tr>
<td>short</td>
<td>SHORT</td>
<td>16-bit signed integer</td>
</tr>
<tr>
<td>unsigned short int</td>
<td>UNSIGNED-SHORT</td>
<td>16-bit unsigned integer</td>
</tr>
</tbody>
</table>
DEFINE PARAMETER statement

Caution:

For CHARACTER parameters, the AVM always passes the routine a pointer to the character or character string value rather than the value itself. If the routine modifies the value, it can also modify the AVM memory outside the bounds of the CHARACTER value with unpredictable results. For this reason, ABL does not allow you to use OUTPUT or RETURN for CHARACTER or LONGCHAR parameters, as well as CHARACTER or LONGCHAR array parameters, and does not recommend you use INPUT–OUTPUT for CHARACTER or LONGCHAR parameters. Rather, pass the character string as a MEMPTR parameter. For more information, see OpenEdge Development: Programming Interfaces.

Note: You cannot use RETURN for any type of array parameter.

To indicate that the DLL or UNIX shared library parameter is a pointer to a value rather than the value itself, use the HANDLE TO option. The HANDLE TO option is required when the DLL routine expects a pointer to the value. Note that the CHARACTER data type implies the HANDLE TO option, whether or not you specify it.
For ActiveX control event procedures, \textit{primitive-type-name} can specify the built-in ABL data type that maps to the COM object data type of an ActiveX event parameter. Table 31 shows how the COM object data types for event parameters (shown as ActiveX data types) map to ABL data types.

Table 31: Data types for ActiveX control event procedures

<table>
<thead>
<tr>
<th>ActiveX data type(^1)</th>
<th>ABL data type</th>
</tr>

DEFINE PARAMETER statement

1. For more information on these data type implementations for COM objects, see OpenEdge Development: Programming Interfaces.

2. For Variant event parameters, the AppBuilder specifies <ANYTYPE> as a placeholder. You must change <ANYTYPE> to the data type that most closely matches the expected value. For more information, see the available documentation on the event parameter.

AS [ CLASS ] { object-type-name }

Defines the parameter as an object reference with the data type of a class or interface. The default value of the parameter is the Unknown value (?). You cannot assign an initial value using the INITIAL option.

object-type-name

Specifies the type name of an ABL or .NET class or interface. Specify an object type name using the syntax described in the Type-name syntax reference entry. With an appropriate USING statement, you can also specify a class or interface name alone, without the qualifying package or namespace.

You cannot directly specify the type name of a .NET mapped object type (such as System.Int32). To define a parameter that matches a .NET mapped type, you must define it as the corresponding ABL primitive type (primitive-type-name).

CLASS

If the specified class or interface type name conflicts with an abbreviation for a built-in primitive type name, such as INT for INTEGER, you must specify the CLASS keyword.

For a class or interface return value, ABL passes an object reference associated with the class or interface, not a class instance itself. For more information on object references, see the Class-based object reference reference entry.

LIKE, CASE SENSITIVE, FORMAT, DECIMALS, INITIAL, COLUMN-LABEL, LABEL, NO-UNDO

For descriptions of these options, see the DEFINE VARIABLE statement reference entry.

EXTENT [ constant ]

Defines the parameter as an array of data elements, where the element data type is specified by the AS primitive-type-name option, the LIKE field option, or the AS object-type-name option. This option can specify an array parameter as either determinate (has a defined number of elements) or indeterminate (has an undefined number of elements). To define a determinate array parameter, specify the EXTENT option with the constant argument. This optional argument is an integer value that represents the number of data elements in the array parameter. To define an indeterminate array parameter, specify the EXTENT option without the constant argument.

The EXTENT is part of the parameter data type. For more information, see the Type-name syntax reference entry.

An indeterminate array parameter can be in one of two states: fixed or unfixed, meaning it either has a fixed dimension or it does not. An indeterminate array parameter has an unfixed dimension when first defined. You can fix the dimension of an unfixed indeterminate array parameter by:

• Setting the number of elements in the array parameter using the EXTENT statement
• Defining the indeterminate array parameter so that it becomes the target of a
determinate array assignment as a passed argument (on INPUT) or as a value
returned from the procedure (on OUTPUT), fixing the indeterminate array to the
dimension of the determinate array assignment

ABL treats a fixed indeterminate array parameter as a determinate array parameter; that is,
its size is fixed. The AVM determines the size of an unfixed indeterminate array parameter
at run time.

You cannot pass an unfixed indeterminate array to a COM object, DLL routine, or UNIX
shared library routine.

If you want to define a parameter that is like an array variable or field, using the LIKE
option, but you do not want the parameter to be an array, you can use EXTENT 0 to
indicate a non-array parameter.

If you are using the AS option and you do not use the EXTENT option (or you specify
constant as 0), the parameter is not an array parameter. If you are using the LIKE field
option and you do not use the EXTENT option, the parameter uses the extent defined for
the database field you name (if any).

PARAMETER BUFFER buffer-name FOR [ TEMP-TABLE ] table-name [ PRESELECT ]

Defines a buffer parameter, where buffer-name is the name you specify for the buffer and
table-name is the name of a temp-table or database table. You can pass a buffer associated
with a database table to a buffer parameter. You cannot pass a work table to a buffer
parameter. A buffer parameter is always INPUT-OUTPUT. You cannot pass buffer
parameters to the AppServer.

Use the TEMP-TABLE option to define a buffer parameter for a temp-table when the
temp-table has the same name as a database table. Otherwise, ABL associates the buffer
with the database table by default. Note that you can define a temp-table buffer parameter
only for an internal procedure that you define in an external procedure where the
temp-table specified by table-name is already defined.

If you use the PRESELECT option and access the buffer parameter in a DO or REPEAT
block, the AVM creates an internal list of the records selected. The PRESELECT option
tells the AVM to apply that internal list to the buffer you define.

TABLE FOR temp-table-name

Defines a temp-table parameter.

You can pass a temp-table parameter to both local and remote procedures. The AVM
passes the parameter by value, by default. That is, the caller and the called routine each
have their own instance of the temp-table. When you invoke the RUN statement, the AVM
deep-copies the parameter from one instance to the other. The table that is copied depends
on whether the parameter is INPUT, OUTPUT, or INPUT-OUTPUT. When you pass a
temp-table as an INPUT parameter, the AVM replaces the receiving instance with the
source instance, by default. You can also append the copied instance to the end of the
receiving instance by specifying the APPEND option. For more information about the
APPEND option, see the option description later in this reference entry.

When passing a temp-table parameter to a local procedure, you can override the default
depth copy and pass the parameter by reference or by binding (that is, by specifying the
parameter in a RUN statement using either the BY-REFERENCE or BIND option). Passing a temp-table parameter by reference or by binding allows the caller and the called routine to access the same object instance (instead of deep-copying the parameter).

**Note:** When you specify the BIND option in the DEFINE PARAMETER statement, you must also specify the BIND option in the RUN statement.

For more information about passing a temp-table parameter by reference or by binding, see the Parameter passing syntax reference entry. For more information about temp-table parameters, see *OpenEdge Getting Started: ABL Essentials*.

**TABLE-HANDLE** `temp-table-handle`

Defines a temp-table handle parameter.

**DATASET** `dataset-name`

Defines a compile-time defined ProDataSet object parameter.

You can pass a ProDataSet object parameter to both local and remote procedures. The AVM passes the parameter by value, by default. That is, the caller and the called routine each have their own instance of the object. When you invoke the RUN statement, the AVM deep-copies the parameter from one instance to the other. The ProDataSet that is copied depends on whether the parameter is INPUT, OUTPUT, or INPUT-OUTPUT. When you pass a ProDataSet as an INPUT parameter, the AVM replaces the receiving instance with the source instance, by default. You can also append the copied instance to the end of the receiving instance by specifying the APPEND option. For more information about the APPEND option, see the option description later in this reference entry.

When passing a ProDataSet object parameter to a local procedure, you can override the default deep copy and pass the parameter by reference or by binding (that is, by specifying the parameter in a RUN statement using either the BY-REFERENCE or BIND option). Passing a ProDataSet object parameter by reference or by binding allows the caller and the called routine to access the same object instance (instead of deep-copying the parameter).

**Note:** When you specify the BIND option in the DEFINE PARAMETER statement, you must also specify the BIND option in the RUN statement.

For more information about passing a ProDataSet object parameter by reference or by binding, see the Parameter passing syntax reference entry. For more information on ProDataSet object parameters, see *OpenEdge Development: ProDataSets*.

**DATASET-HANDLE** `dataset-handle`

Defines a ProDataSet object handle parameter.

**APPEND**

Specifies whether or not to append the data from a source instance to the receiving instance of a passed temp-table or ProDataSet parameter. To append input parameter data, specify the APPEND option in the DEFINE PARAMETER statement. To append output parameter data, specify the APPEND option in the RUN statement.
BIND

Indicates that a TABLE, TABLE-HANDLE, DATASET, or DATASET-HANDLE parameter binds a reference-only object in one routine to an object instance defined and instantiated in another local routine.

When you define a reference-only object in the calling routine, and you want to bind that object definition to an object instance in the called routine, define the parameter by specifying the BIND option in an INPUT or INPUT-OUTPUT parameter definition. When you define a reference-only object in the called routine, and you want to bind that object definition to an object instance in the calling routine, define the parameter by specifying the BIND option in an OUTPUT parameter definition. In either case, the reference-only object definition remains bound to the object instance until the routine containing the reference-only object definition is deleted or terminates.

**Caution:** Do not delete the object or routine to which a reference-only object is bound, or you might be left with references to an object that no longer exists.

You can bind multiple reference-only object definitions to the same object instance. You can also bind a single reference-only object definition to the same object instance multiple times without generating an error. However, you cannot bind a single reference-only object definition to multiple object instances.

When passing one of these parameters to a remote procedure, the AVM ignores the BIND option and deep-copies the parameter based on the specified parameter mode.

For more information about passing these parameters by binding, see the Parameter passing syntax reference entry.

BY-VALUE

Specified for an INPUT, OUTPUT, or INPUT-OUTPUT TABLE, TABLE-HANDLE, DATASET, or DATASET-HANDLE parameter in a called routine, this option forces the parameter to be passed to the local routine by value, which overrides any BY-REFERENCE option in the corresponding routine invocation. For more information on BY-REFERENCE, see the Parameter passing syntax reference entry.

**Examples**

In the following examples, the `r-runpar.p` procedure runs a subprocedure called `r-param.p` and passes the subprocedure an INPUT parameter. The subprocedure `r-param.p` displays the INPUT parameter.

**r-runpar.p**

```plaintext
RUN r-param.p (INPUT 10).
```

**r-param.p**

```plaintext
DEFINE INPUT PARAMETER int-param AS INTEGER NO-UNDO.
DISPLAY int-param LABEL "Integer input param"
   WITH SIDE-LABELS.
```
In the following example, the \texttt{r-runpr1.p} procedure runs a subprocedure called \texttt{r-param1.p}. This example illustrates the use of multiple parameters and shows that the parameters must be passed in the proper order and must be of the same data type. Note that if you do not specify a parameter type in the RUN statement, the AVM assumes it is an input parameter.

\textbf{r-runpr1.p}

```plaintext
DEFINE VARIABLE new-param AS CHARACTER NO-UNDO FORMAT "x(20)".
DEFINE VARIABLE out-param AS DECIMAL NO-UNDO.
DEFINE VARIABLE in-param AS INTEGER NO-UNDO INITIAL 20.

RUN r-param1.p (OUTPUT out-param, 10, OUTPUT new-param, in-param).
DISPLAY out-param LABEL "Updated YTD Sales" SKIP new-param LABEL "Status"
WITH SIDE-LABELS.
```

\textbf{r-param1.p}

```plaintext
DEFINE OUTPUT PARAMETER xout-param AS DECIMAL NO-UNDO.
DEFINE INPUT PARAMETER newin AS INTEGER NO-UNDO.
DEFINE OUTPUT PARAMETER xnew-param AS CHARACTER NO-UNDO.
DEFINE INPUT PARAMETER xin-param AS INTEGER NO-UNDO.

FOR EACH Customer NO-LOCK:
  xout-param = xout-param + Customer.Balance.
END.

DISPLAY xout-param LABEL "Balance" WITH SIDE-LABLES.
ASSIGN
  xout-param = xout-param + newin + xin-param
  xnew-param = "Example Complete".
```

In the following example, the \texttt{r-runpr2.p} procedure displays information from a database table and assigns the value of a database field to a variable called \texttt{io-param}. The variable is passed as an INPUT-OUTPUT parameter to a subprocedure called \texttt{r-param2.p}. The subprocedure \texttt{r-param2.p} performs a calculation on the INPUT-OUTPUT parameter, then passes it back to the main procedure. The \texttt{r-runpr2.p} assigns the value \texttt{io-param} to a database field, then displays \texttt{io-param}.

\textbf{r-runpr2.p}

```plaintext
DEFINE VARIABLE io-param AS INTEGER NO-UNDO.

FOR EACH Item:
  DISPLAY Item.ItemName Item.OnHand WITH 1 DOWN.
RUN r-param2.p (INPUT-OUTPUT io-param).
DISPLAY io-param LABEL "New Quantity On-hand".
END.
```

\textbf{r-param2.p}

```plaintext
DEFINE INPUT-OUTPUT PARAMETER io-param AS INTEGER NO-UNDO.

DEFINE VARIABLE inp-qty AS INTEGER NO-UNDO.
PROMPT-FOR inp-qty LABEL "Quantity Received?".
ASSIGN inp-qty.
  io-param = io-param + inp-qty.
```
The following example uses a buffer parameter. The procedure `r-bufp.p` passes the Customer buffer to the `getCustomer` internal procedure, which attempts to find a record using that buffer.

```
r-bufp.p
```

```
DEFINE BUTTON btnFind LABEL "Find Customer".

DO WITH FRAME frCustomer WITH SIDE-LABELS:
   ENABLE Customer.CustNum btnFind.

   ON CHOOSE OF btnFind DO:
      IF NOT ERROR-STATUS:ERROR THEN
         DISPLAY Customer EXCEPT Customer.Comments WITH SIDE-LABELS.
      END.

   ON ENTRY OF Customer.CustNum
      HIDE MESSAGE.
   END.

   WAIT-FOR WINDOW-CLOSE OF CURRENT-WINDOW.

PROCEDURE getCustomer:
   DEFINE INPUT PARAMETER hWidget  AS HANDLE NO-UNDO.
   DEFINE PARAMETER BUFFER bufCustomer FOR Customer.

   FIND bufCustomer WHERE bufCustomer.CustNum =
      INTEGER(hWidget:SCREEN-VALUE) NO-LOCK NO-ERROR.
   IF NOT AVAILABLE bufCustomer THEN DO:
      MESSAGE "Customer record not found." VIEW-AS ALERT-BOX.
      RETURN ERROR.
   END.

END.
```

The following example defines parameters for the DLL routine, `MessageBox`, which displays a message on the screen:

```
r-dllex1.p
```

```
DEFINE VARIABLE result AS INTEGER NO-UNDO.

MESSAGE " It's a whole new world!"
   VIEW-AS ALERT-BOX MESSAGE BUTTONS OK TITLE "ABL Message".

RUN MessageBoxA (0, " It's a whole new world, again!!", 
   "ABL DLL access", 0, OUTPUT result).

PROCEDURE MessageBoxA EXTERNAL "user32.dll":
   DEFINE INPUT PARAMETER hwnd AS LONG.
   DEFINE INPUT PARAMETER mbtext AS CHARACTER.
   DEFINE INPUT PARAMETER mbtitle AS CHARACTER.
   DEFINE INPUT PARAMETER style AS LONG.
   DEFINE RETURN PARAMETER result AS LONG.
END.
```

### Notes
- All procedure parameters are normally passed by value, by default. This means that for any INPUT-OUTPUT or OUTPUT parameter, the field or variable that receives the output value is not set by the called procedure until the procedure returns without error. An exception is made for local DATASET, DATASET-HANDLE, TABLE, and TABLE-HANDLE parameters, which you may pass by reference or by binding by specifying the parameter in a RUN statement using either the BY-REFERENCE or BIND...
DEFINE PARAMETER statement

option. If you specify the BIND option in the RUN statement, you must also specify the
BIND option in the DEFINE PARAMETER statement.

For more information about passing parameters by reference or by binding, see the
Parameter passing syntax reference entry.

- You cannot pass a BLOB or CLOB field as a parameter. To pass a BLOB or CLOB field
  as a parameter, you must include the field in a temp-table or convert the field to its
  MEMPTR or LONGCHAR counterpart, respectively.
- Buffer parameters are scoped in the same way as shared buffers. They also affect cursors
defined in the calling procedure in the same way as shared buffers.
- For DLL or UNIX shared library routine declarations:
  - The LIKE field option can only specify a database field of type CHARACTER or
    a variable of type CHARACTER or MEMPTR.
  - The COLUMN, COLUMN-LABEL, DECIMALS, INITIAL, FORMAT, LABEL,
    and NO-UNDO options have no effect.
- You cannot pass a DATE, DATETIME, or DATETIME-TZ as a parameter to or from a
  DLL routine or a UNIX shared library routine.
- You can pass a LONGCHAR as a parameter to a DLL routine or a UNIX shared library
  routine. When passing a LONGCHAR parameter, the AVM passes only the text string (not
  the code page information). You are responsible for setting the code page of a
  LONGCHAR parameter.
- You can pass an array of type INTEGER, INT64, or DECIMAL as a parameter to or from
  a DLL routine or a UNIX shared library routine. You can pass an array of type
  CHARACTER to (not from) a DLL routine or a UNIX shared library routine.
- You cannot pass a variable or array that contains the Unknown value (?) to a DLL.
- RETURN parameters are supported only for DLL or UNIX shared library routines. The
  RETURN parameter type must match the OUTPUT parameter that returns the DLL
  function value in the RUN statement for the routine. You cannot pass an array as a
  RETURN parameter to DLL or UNIX shared library routines. Use a MEMPTR instead.
- If you specify a RETURN parameter as MEMPTR to return a character string, use the
  GET-STRING function to extract the CHARACTER value.
- For more information on DLL routine parameters and how they map to ABL data types,
  see the chapter on DLLs in OpenEdge Development: Programming Interfaces.
- You cannot pass a MEMPTR as a parameter to or from a COM object.
- You can pass a LONGCHAR, a DATETIME, a DATETIME-TZ, and an array as a
  parameter to or from a COM object.

When passing a LONGCHAR parameter to a COM object, the AVM passes only the text
string (not the code page information). When receiving a text string from a COM object
into a LONGCHAR parameter, the AVM converts the text string to the code page
associated with the LONGCHAR parameter only if the LONGCHAR has a fixed code
DEFINE PARAMETER statement

page. Otherwise, the AVM sets the LONGCHAR code page to UTF-16. If the AVM cannot convert a LONGCHAR, it raises a run-time error.

When passing a DATETIME or DATETIME-TZ parameter to a COM object, the AVM represents the time to the millisecond. When passing a DATETIME-TZ parameter to a COM object, the AVM first converts the DATETIME-TZ value relative to the local session’s date and time, and then drops the time zone.

When receiving a date from a COM object into a DATETIME or DATETIME-TZ parameter, the AVM represents the time to the millisecond. When receiving a date from a COM object into a DATETIME-TZ parameter, the AVM sets the time zone to the local session’s time zone.

• For more information on ActiveX event parameters, or using COM objects, see the chapter in OpenEdge Development: Programming Interfaces.

• For dynamic temp-table parameters:
  – If the parameter is INPUT TABLE-HANDLE, the temp-table definition behind the handle plus the temp-table contents are sent from the caller to the called routine. The called routine may have either the dynamic INPUT TABLE-HANDLE or the compile-time defined INPUT TABLE as a matching parameter.
  – When running remotely with the AppServer, if the parameter is INPUT TABLE-HANDLE, a new instance of the temp-table is created along with its handle, completely separate from the caller’s table, and is populated with the contents from the caller’s table.

You can override this default behavior to allow the calling procedure and the called procedure to access the same object instance by passing the TABLE-HANDLE parameter by reference or by binding (that is, by specifying the parameter in a RUN statement using either the BY-REFERENCE or BIND option). If you specify the BIND option in the RUN statement, you must also specify the BIND option in the DEFINE PARAMETER statement.

  – The OUTPUT TABLE-HANDLE parameter, just like any other OUTPUT variable, cannot change the data in the caller procedure: in this case, the definition of the temp-table.
  – If the parameter is OUTPUT TABLE-HANDLE, the called routine sends back the definition behind the handle along with the contents of the output temp-table. In the caller, if the original handle was the Unknown value (?), a new instance of the temp-table is created and populated with the output contents. The temp-table object is created in the default widget-pool of the caller’s OpenEdge session. To avoid memory leaks, the temp-table object must be manually destroyed. For more information on deleting objects, see the reference entry for the DELETE OBJECT statement.

If the original handle is not the Unknown value (?), the caller’s existing table must match the table being received from the called routine.

  – If the APPEND option is used, the new data is added to the existing table’s data.
  – If the parameter is INPUT-OUTPUT TABLE-HANDLE, a combination of the above occurs.
If you call a remote procedure asynchronously (using the ASYNCHRONOUS option of the RUN statement) and pass a parameter as OUTPUT TABLE-HANDLE \texttt{temp-table-handle} APPEND, the event procedure must specify a corresponding DEFINE INPUT PARAMETER TABLE-HANDLE FOR \texttt{temp-table-handle} APPEND statement, and \texttt{temp-table-handle} must be global to both the calling procedure and the event procedure.

- If you define an INPUT TABLE parameter for an asynchronous event procedure with a data type that is different from the data type of the corresponding OUTPUT TABLE parameter passed from the AppServer, any failure to convert the passed value causes the event procedure to fail and the AVM to display an error message on the client.

- The AVM creates the temp-table object for an OUTPUT TABLE-HANDLE parameter in the session’s default widget pool. Remember to delete this object at the appropriate point to avoid memory leaks.

- You cannot specify a ProDataSet object or ProDataSet object handle as a parameter for an asynchronous remote procedure.

- For more information on working with asynchronous remote procedures and event procedures, see \textit{OpenEdge Application Server: Developing AppServer Applications}.

- For dynamic ProDataSet object parameters:
  - If the parameter is INPUT DATASET-HANDLE, the ProDataSet object definition behind the handle plus the ProDataSet object contents are sent from the caller to the called routine. The called routine may have either the dynamic INPUT DATASET-HANDLE or the compile-time defined INPUT DATASET as a matching parameter.
  - If the parameter is INPUT DATASET-HANDLE, a new instance of the ProDataSet object is created along with its handle, completely separate from the caller’s table, and is populated with the contents from the caller’s table.

    You can override this default behavior to allow the calling procedure and the called procedure to access the same object instance by passing the DATASET-HANDLE parameter by reference or by binding (that is, by specifying the parameter in a RUN statement using either the BY-REFERENCE or BIND option). If you specify the BIND option in the RUN statement, you must also specify the BIND option in the DEFINE PARAMETER statement.

    - If the parameter is OUTPUT DATASET-HANDLE, the handle plus the definition behind the handle are sent from the caller to the called routine. The called routine may have either the dynamic OUTPUT DATASET-HANDLE or the compile-time defined OUTPUT DATASET as a matching parameter.

      If the parameter is OUTPUT DATASET-HANDLE, and the caller’s handle is the Unknown value (?), no definition is sent to the called routine.

      - If the parameter is OUTPUT DATASET-HANDLE, the called routine sends back the definition behind the handle along with the contents of the output ProDataSet object. In the caller, if the original handle is the Unknown value (?), a new instance of the ProDataSet object is created and populated with the output contents. If the original handle is not the Unknown value (?), the caller’s existing object must match the object being received from the called routine.
DEFINING PROPERTY statement

- If the APPEND option is used, the new data is added to the existing object’s data.
- If the parameter is INPUT-OUTPUT DATASET-HANDLE, a combination of the above occurs.

- A BUFFER parameter cannot be a REFERENCE-ONLY buffer or a BEFORE-TABLE buffer. The use of them as a BUFFER type of parameter (as opposed to INPUT or OUTPUT) is a compiler error. Instead of passing the buffer, the buffer's table can be passed by-reference.

See also DEFINE BUFFER statement, DEFINE VARIABLE statement, DELETE PROCEDURE statement, Parameter passing syntax, RUN statement, Type-name syntax, USING statement

DEFINE PROPERTY statement

Defines a property of a class, declares a property prototype in an ABL interface, or overrides an abstract property inherited from an ABL or .NET abstract super class. A property is a named member of a class that allows you to read or write a value using the same syntax as a data member. However, a property can define special methods (accessors) that specify if and how the property can be read or written. The following description begins with the syntax for defining a property that you can both read and write.

**Note:** This statement is applicable only when used in a class or interface definition (.cls) file.

**Syntax**

```plaintext
DEFINE [ PRIVATE | PROTECTED | PUBLIC ] [ STATIC | ABSTRACT ] [ OVERRIDE ]
PROPERTY property-name
{
  {
    AS primitive-type-name |
    AS [ CLASS ] object-type-name
  } [ EXTENT [ constant ] ]
  [ INITIAL [ constant | { constant [ , constant ] . . . ] } ] ]
  [ NO-UNDO ]
  {
    [ accessor-access-mode ] GET [ implementation ] .
    SET [ implementation ] .
  | [ accessor-access-mode ] SET [ implementation ] .
  }
```

Use the following syntax to define a property that you can read only:
DEFINE PROPERTY statement

```
DEFINE [ PRIVATE | PROTECTED | PUBLIC ] [ STATIC | ABSTRACT ] [ OVERRIDE ]
PROPERTY property-name
  {  
    AS primitive-type-name |  
    AS [ CLASS ] object-type-name  
  } [ EXTENT [ constant ] ]  
[ INITIAL { constant | { [constant [, constant] ...] } } ]  
[ NO-UNDO ]
GET [ implementation ] .
```

Use the following syntax to define a property that you can write only:

```
DEFINE [ PRIVATE | PROTECTED | PUBLIC ] [ STATIC | ABSTRACT ] [ OVERRIDE ]
PROPERTY property-name
  {  
    AS primitive-type-name |  
    AS [ CLASS ] object-type-name  
  } [ EXTENT [ constant ] ]  
[ INITIAL { constant | { [constant [, constant] ...] } } ]  
[ NO-UNDO ]
SET [ implementation ] .
```

Use the following syntax to declare an interface property prototype:

```
DEFINE [ PUBLIC ] PROPERTY property-name
  {  
    AS primitive-type-name | AS [ CLASS ] object-type-name  
  } [ EXTENT [ constant ] ] [ NO-UNDO ]
{  
  GET.  
{  
  SET.  
{  
  GET.  
{  
  SET.  
```

Use the following syntax to declare an abstract property prototype:
 DEFINE [ PROTECTED | PUBLIC ] [ OVERRIDE ] ABSTRACT PROPERTY property-name 
{ { AS primitive-type-name | AS [ CLASS ] object-type-name } 
[ EXTENT [ constant ] ] [ NO-UNDO ] } 
{ GET. 
| SET. 
| GET. 
| SET. }

[ PRIVATE | PROTECTED | PUBLIC ]

Specifies the access mode for the property. A PRIVATE property can be accessed only by the defining class. A PROTECTED property can be accessed by the defining class and any of its derived classes. A PUBLIC property can be accessed by:

- The defining class
- Any of its derived classes
- Any class or procedure that has access to a class instance that defines or inherits the property

Any piece of code can access a PUBLIC static property. The default access mode is PUBLIC.

This access mode applies to both reading and writing the property value by default. However, you can set a different access mode for reading or writing the property value (but not both) using an appropriate accessor-access-mode option to define the corresponding accessor (GET or SET).

When declaring an interface property prototype, the access mode for the property must be PUBLIC (the default).

When defining an abstract property, the access mode for the property cannot be PRIVATE.

[ STATIC ]

Defines a property that is a static member of the class type for which it is defined and that is scoped to the ABL session where it is referenced. ABL creates one copy of the specified class static property on first reference to the class type, and ABL creates only one such copy for any number of instances of the class that you create. You can reference an accessible static property in any piece of code.

Without this option, ABL defines an instance property that is scoped to a single instance of the class where it is defined. ABL creates one copy of the specified instance property for each such class instance that you create. You can reference any public instance property (abstract or non-abstract) in any procedure, or in any instance or static method defined inside or outside of the class where the instance property is defined. Any static method can reference the public instance property only using an object reference to a class instance that defines the property as a member. If the referencing static method is defined
in the same class as the public instance property, the class must instantiate itself in order to have access to an instance reference.

You can reference a private or protected instance property only in instance methods that are defined inside the same class or class hierarchy.

**Note:** You cannot use a class instance that is not equal to the THIS-OBJECT system reference to reference a private or protected instance property that is defined in the same class, because PRIVATE and PROTECTED access modes are instance based in ABL. Thus, private and protected instance members are accessible only to other members of the same class instance, where as public instance members can be accessed from other instances of the same class, including the session “static instance” of the class.

For more information on the mechanism for accessing properties of different access modes and scopes, see the reference entry for Class-based property access.

The STATIC option is not valid when you:

- Define or implement an abstract property
- Declare an interface property prototype
- Implement an interface property

**[ ABSTRACT ]**

Defines the property as an abstract member of the class type for which it is defined. The defining class type must also be abstract. If you define an abstract property, it has the following requirements:

- You must specify the OVERRIDE option if an inherited abstract property has the same name and data type.
- You can specify either a PROTECTED or a PUBLIC access mode, depending on any inherited abstract property you might be overriding.
- The abstract property must be overridden and implemented in a derived class.

Any class definition for an instance property that includes the OVERRIDE option and does not include the ABSTRACT option defines a property implementation. If it also includes the ABSTRACT option, the inherited abstract property remains abstract.

This option is not valid either when you define a static property or when you declare an interface property prototype.

**[ OVERRIDE ]**

Specifies that this instance property overrides an abstract property inherited from an ABL or .NET abstract class.

**Note:** A .NET abstract property or class is defined in C# with the abstract keyword.
When you specify OVERRIDE, the property definition must match the inherited abstract property with respect to name, data type (including any EXTENT), specified accessors (GET or SET), and NO-UNDO setting. In addition, the access mode must not be more restrictive than the access mode defined for the overridden property. When overriding a .NET abstract property, the data type must also map appropriately to the inherited .NET property data type. For more information, see the description of the primitive-type-name and object-type-name options.

If you specify the ABSTRACT option, your overriding property is also defined as abstract, and it must be implemented in a class derived from the defining class. Note that you do not have to override an inherited abstract property that you want to remain abstract as long as the inheriting class is also abstract. However, doing so allows you to specify a less restrictive access mode for the abstract property.

If you do not specify the ABSTRACT option, your property definition implements the inherited abstract property.

This option is not valid:

- When you define a static property
- When you declare an interface property prototype
- To override an inherited property that is implemented (not abstract)

property-name

Specifies the name of the property. The property-name must be unique among the names of all properties, events, and variable data members that are defined in the class and its inherited class hierarchy, and that are accessible to the defining class (not defined as PRIVATE in a super class).

Note: Members of a class are grouped into six namespaces, including buffers/temp-tables, methods, variables/properties/events, ProDataSets, queries, and data-sources. Variables, properties, and events defined as members of a class share the same namespace. There can be only one class member in this namespace with a given name (not counting abstract member overrides).

You can reference this name from outside the property definition in order to read a value from or write a value to the property. You can reference this name from inside the property definition (in a GET or SET accessor) in order to read or write the value of the default memory for the property, according to its data type.

Note: If the property is defined in a class that is derived from a .NET class, other restrictions on property-name apply. For more information, see the CLASS statement reference entry.

AS primitive-type-name

Specifies a built-in primitive type (primitive-type-name) and an optional initial value (constant) for the default memory of the property. The built-in data type can be one of the following:
If you are overriding a .NET abstract property or implementing a property defined in a .NET interface, `primitive-type-name` must specify the exact same .NET mapped data type that is defined for the corresponding .NET property. For a .NET mapped data type that is a default match for a given ABL primitive type, you must use the default matching ABL data type, as shown in Table 23. (For example, `INTEGER` indicates a .NET System.Int32.) For a .NET mapped data type that is not a default match for one of the ABL primitive types, ABL provides a data type keyword (`AS-data-type`) that you must use to explicitly indicate the required .NET data type, as shown in Table 24. (For example, the AS data type, `UNSIGNED-BYTE`, indicates a .NET System.Byte.)

**Note:** At run time, a property defined using an `AS-data-type` keyword behaves in ABL like the corresponding ABL primitive type shown in Table 24. (For example, an `UNSIGNED-BYTE` behaves like an `INTEGER`.)

Also note that when implementing a .NET array property, you must specify the .NET array object type (for example, "System.Int32[]" or "System.Byte[]"); you **cannot** use an ABL array equivalent (such as `INTEGER EXTENT` or `UNSIGNED-BYTE EXTENT`).

These are the same set of primitive types that can be specified for the return type of a method. Thus, for example, a property cannot have a complex type such as a temp-table, ProDataSet, or any other data type that is invalid as a method return type. For more information on these primitive types, see the Data types reference entry.

**Note:** To manage public access for a complex data type that cannot be specified for a property, you can define both a data member of that complex type and a separate public method that passes the complex type as a parameter.

### Syntax

```
CHARACTER | COM-HANDLE | DATE | DATETIME | DATETIME-TZ | DECIMAL
| HANDLE   | INT64   | INTEGER | LOGICAL | LONGCHAR | MEMPTR | RAW | RECID
| ROWID    | AS-data-type
```

If you are overriding a .NET abstract property or implementing a property defined in a .NET interface, `object-type-name` must specify the exact same .NET object type that is defined for the corresponding .NET property. For a .NET mapped data type that is a default match for a given ABL primitive type, you must use the default matching ABL data type, as shown in Table 23. (For example, `INTEGER` indicates a .NET System.Int32.) For a .NET mapped data type that is not a default match for one of the ABL primitive types, ABL provides a data type keyword (`AS-data-type`) that you must use to explicitly indicate the required .NET data type, as shown in Table 24. (For example, the AS data type, `UNSIGNED-BYTE`, indicates a .NET System.Byte.)

**Note:** At run time, a property defined using an `AS-data-type` keyword behaves in ABL like the corresponding ABL primitive type shown in Table 24. (For example, an `UNSIGNED-BYTE` behaves like an `INTEGER`.)

Also note that when implementing a .NET array property, you must specify the .NET array object type (for example, "System.Int32[]" or "System.Byte[]"); you **cannot** use an ABL array equivalent (such as `INTEGER EXTENT` or `UNSIGNED-BYTE EXTENT`).

These are the same set of primitive types that can be specified for the return type of a method. Thus, for example, a property cannot have a complex type such as a temp-table, ProDataSet, or any other data type that is invalid as a method return type. For more information on these primitive types, see the Data types reference entry.

**Note:** To manage public access for a complex data type that cannot be specified for a property, you can define both a data member of that complex type and a separate public method that passes the complex type as a parameter.

### Syntax

```
CHARACTER | COM-HANDLE | DATE | DATETIME | DATETIME-TZ | DECIMAL
| HANDLE   | INT64   | INTEGER | LOGICAL | LONGCHAR | MEMPTR | RAW | RECID
| ROWID    | AS-data-type
```

If you are overriding a .NET abstract property or implementing a property defined in a .NET interface, `object-type-name` must specify the exact same .NET object type.
as the corresponding interface property. However, for .NET inner (nested) type, note the difference in the ABL syntax, which replaces the corresponding period (.) in the .NET object type with a plus (+) (see the Type-name syntax reference entry).

Also note that when implementing a .NET array property, you must specify the exact .NET array object type (for example, "System.Drawing.Point[]"); you cannot use an ABL array equivalent (such as System.Drawing.Point EXTENT).

**CLASS**

If the specified class or interface type name conflicts with an abbreviation of a built-in primitive type name, such as INT for INTEGER, you must specify the CLASS keyword.

For more information on object references, see the Class-based object reference reference entry.

```
[ EXTENT [ constant ] ]
```

Defines the property as an array of data elements, where the element data type is specified by either the AS primitive-type-name option or the AS object-type-name option. This option can specify an array property as either determinate (has a defined number of elements) or indeterminate (has an undefined number of elements). To define a determinate array property, specify the EXTENT option with the constant argument. This optional argument is an integer value that represents the number of elements in the property array. To define an indeterminate array property, specify the EXTENT option without the constant argument.

The EXTENT is part of the property data type. For more information, see the Type-name syntax reference entry.

An indeterminate array property can be in one of two states: fixed or unfixed, meaning it either has a fixed dimension or it does not. An indeterminate array property has an unfixed dimension when first defined. You can fix the dimension of an indeterminate array property by:

- Initializing the array values when you define the property, using the INITIAL option
- Setting the number of elements in the array property using the EXTENT statement
- Assigning a determinate array to the indeterminate array, fixing it to the dimension of the determinate array
- Passing array parameters to a procedure, user-defined function, or class-based method, so that the indeterminate array property is the target for the passing of a determinate array, fixing the indeterminate array to the dimension of the determinate array

Once fixed, ABL treats a fixed indeterminate array as a determinate array.

If you do not use the EXTENT option (or you specify constant as 0), the property is not an array property.
DEFINE PROPERTY statement

\[
\text{[ INITIAL \{ constant | [ constant , constant ] \ldots \} ] }
\]

The initial value of the property you want to define. If you use the AS primitive-type-name option and you do not use the INITIAL constant option, the initial value is the default initial value for the data type of the variable or array element.

When you define an array property, you can supply initial values for each element in the array. For example:

```sql
DEFINE VARIABLE array-var AS CHARACTER NO-UNDO EXTENT 3
  INITIAL ["Add","Delete","Update"].
```

If you do not supply enough values to fill up the elements of the array, the AVM puts the last value you named into the remaining elements of the array. If you supply too many values, the AVM raises an error.

If you define a property as an indeterminate array, and you supply initial values for elements in the array, the AVM fixes the number of elements in the array and treats the fixed indeterminate array as a determinate array. For example, the arrays defined by the following statements are equivalent:

```sql
DEFINE VARIABLE x AS INTEGER NO-UNDO EXTENT INITIAL [1,2,3].
DEFINE VARIABLE x1 AS INTEGER NO-UNDO EXTENT 3 INITIAL [1,2,3].
```

You can also use the EXTENT statement to fix the number of elements in an unfixed indeterminate array variable. For more information, see the EXTENT statement reference entry.

The INITIAL option is not valid either when you define an abstract property or when you declare an interface property prototype.

Table 35 lists the default initial values for the various property data types.

**Table 32: Default variable initial values**

<table>
<thead>
<tr>
<th>Data type</th>

</tr>
</tbody>
</table>

(1 of 2)
When the value of a property is changed during a transaction and the transaction is undone, the AVM restores the value of the property to its prior value. If you do not want, or if you do not need, the value of such a property to be undone even when it has been changed during a transaction, use the NO-UNDO option. NO-UNDO properties are more efficient; use this option whenever possible.

`[ NO-UNDO ]`

When the value of a property is changed during a transaction and the transaction is undone, the AVM restores the value of the property to its prior value. If you do not want, or if you do not need, the value of such a property to be undone even when it has been changed during a transaction, use the NO-UNDO option. NO-UNDO properties are more efficient; use this option whenever possible.

`[ accessor-access-mode ]`

Specifies the access mode for the immediately following accessor (GET or SET). The possible access modes include:

**Syntax**

| PROTECTED | PRIVATE |

To use an `accessor-access-mode` with accessors:

- You must define at least one accessor (GET or SET) that defaults to the access mode of the property. Therefore, if you define only one accessor, you cannot specify a separate `accessor-access-mode` for it.

- If you define two accessors, you can specify an `accessor-access-mode` for one of the accessors, but only if this `accessor-access-mode` is more restrictive than the access mode of the property.

- If you are defining an abstract property, you cannot specify the PRIVATE access mode for an accessor.

</tbody>
</table>

1. If you display a class instance using the MESSAGE statement, ABL automatically invokes the ToString( ) method (provided by the Progress.Lang.Object class) on the object reference. To display a class instance in a frame (for example, using the DISPLAY statement), you must first explicitly convert the object reference to a displayable type using the INT64 function, the INTEGER function, the STRING function, or the ToString( ) method.

2. You cannot use the INITIAL option to specify an initial value for this data type as part of the property definition.
So, if the property access mode is PUBLIC, any accessor-access-mode that you specify must be either PROTECTED or PRIVATE; if the property access mode is PROTECTED, any accessor-access-mode that you specify must be PRIVATE, unless the property is abstract.

**GET [ implementation ].**

An accessor (GET) that defines the property as_readable_. If you do not define a GET accessor for a class property, the property cannot be read, not even from within the defining class.

It is valid to omit the GET accessor when defining a property for an interface. It is then up to the class implementing the interface to decide whether to define the GET accessor for the property or not. However, as stated above, if you do not define a GET accessor for a class property, the property cannot be read. If you do not define a GET accessor, then you **must** define a SET accessor.

You can define a GET accessor using two basic forms: with or without an implementation. However, if you are defining an abstract property or an interface property prototype, you cannot define the GET accessor with an implementation. This is the syntax for a GET accessor **with** an implementation:

**Syntax**

```
GET ([ array-index-parameter ]) : get-logic END [ GET ].
```

**array-index-parameter**

Specifies an INPUT parameter that provides access to the index value of the current element of an array property from within the get-logic. When a property is defined as an array using the EXTENT option, the GET accessor references the single element of the property array. The array-index-parameter specifies the subscript value for the element being accessed. This is the syntax:

**Syntax**

```
INPUT array-index-name AS { INTEGER | INT64 }
```

**array-index-name**

Specifies the name of the INPUT parameter that provides the subscript value (index) for this array element. You must use this value in a subscript on the property name (property-name[ array-index-name ]) to access the default memory for the current array element.

**INTEGER | INT64**

Specifies the data type of the index. Use the data type that supports the largest dimension that is defined for or that you expect to be fixed for the property array at run time.

Where supported, an unsubscripted array reference is a reference to the whole array. For a property array, an unsubscripted read reference invokes the GET accessor for each array element in ascending order by subscript value.
DEFINE PROPERTY statement

get-logic

Can contain ABL code that executes for any operation that reads the property from outside its own GET accessor definition. This code can include any ABL statements that are valid in a method of a class, including CATCH and FINALLY blocks, except statements that block for input. However, if you define the property itself as static, you cannot access any instance members of classes (including the defining class) or use the SUPER and THIS-OBJECT system references; you can only access static class members and the local data elements of the GET accessor. The actual value that you return from the property is entirely dependent on your get-logic code. Within get-logic, any operation that reads from property-name (such as the right-hand side of an assignment) directly reads the value of the property’s default memory. However, any operation that writes to property-name within get-logic invokes the property’s own SET accessor to assign the value, exactly like writing the property from outside of its own definition. If the SET accessor is defined with an implementation, that implementation determines how the value is written to the property.

You do not have to use the property’s default memory to provide the value read from a property. You can also use any other accessible data, such as a data member, as storage to access property values. To return a value from get-logic to any outside reader of the property, you must return a value with the correct data type using the RETURN statement (similar to any method that returns a value). If you do not invoke the RETURN statement in get-logic, the property returns the Unknown value (?).

This is the syntax for a GET accessor without an implementation:

Syntax

GET.

Without an implementation, an operation that reads the property directly accesses the current value in the property’s default memory.

If the property is an array, the default accessor implementation handles the subscript references automatically. Providing an array-index-parameter in this case is a compiler error.

SET [implementation].

An accessor (SET) that defines the property as writable. If you do not define a SET accessor, the property cannot be written, not even from within the defining class. You can define a SET accessor using two basic forms: with or without an implementation.

It is valid to omit the SET accessor when defining a property for an interface. It is then up to the class implementing the interface to decide whether to define the SET accessor for the property or not. However, as stated above, if you do not define a SET accessor for a class property, the property cannot be written. If you do not define a SET accessor, then you must define a GET accessor.

You can define a SET accessor using two basic forms: with or without an implementation. However, if you are defining an abstract property or an interface property prototype, you cannot define the SET accessor with an implementation. This is the syntax for a SET accessor with an implementation:
DEFINE PROPERTY statement

Syntax

SET ( parameter-definition [, array-index-parameter ] ) :
    set-logic END [ SET ] .

parameter-definition

Specifies an INPUT parameter that provides access to the value written to the
property from within the set-logic. The set-logic can contain ABL code that
executes for any operation that writes to the property from outside its own SET
accessor definition. This code can include any ABL statements that are valid in a
method of a class, including CATCH and FINALLY blocks, except statements that
block for input. However, if you define the property itself as static, you cannot access
any instance members of classes (including the defining class) or use the SUPER and
THIS-OBJECT system references; you can only access static class members and the
local data elements of the SET accessor. To access the value being written to the
property, specify parameter-definition using the following syntax:

Syntax

INPUT parameter-name AS
    { primitive-type-name | [ CLASS ] object-type-name }

INPUT parameter-name

    Specifies the name of the INPUT parameter that you reference in set-logic to
    obtain the value written to the property.

    AS { primitive-type-name | [ CLASS ] object-type-name }

    Specifies the data type of the parameter as a built-in primitive type
    (primitive-type-name), or as a built-in or user-defined object type
    (object-type-name). You must specify exactly the same data type as you
    have defined for the property.

array-index-parameter

Specifies an INPUT parameter that provides access to the index value of the current
element of an array property from within the set-logic. When a property is defined
as an array using the EXTENT option, the SET accessor references a single element
of the property array. The array-index-parameter specifies the subscript value for
the element being accessed. This is the syntax:

Syntax

INPUT array-index-name AS { INTEGER | INT64 }

array-index-name

    Specifies the name of the INPUT parameter that provides the subscript value
    (index) for this array element. You must use this value in a subscript on the
    property name (property-name[array-index-name]) to access the default
    memory for the current array element.
INTEGER | INT64

Specifies the data type of the index. Use the data type that supports the largest dimension that is defined for or that you expect to be fixed for the property array at run time.

Where supported, an unsubscripted array reference is a reference to the whole array. For a property array, an unsubscripted write reference invokes the SET accessor for each array element in ascending order by subscript value.

**set-logic**

Can contain ABL code that accesses the value written to the property as *parameter-name*, then uses *parameter-name* (if you choose) to set the new value for the property. The actual value that you use to set the property is entirely dependent on your *set-logic* code. Within *set-logic*, any operation that writes to *property-name* (such as the left-hand side of an assignment) directly writes the specified value to the property’s default memory. However, any operation that reads from *property-name* within *set-logic* invokes the property’s own GET accessor to read the value, exactly like reading the property from outside of its own definition. If the GET accessor is defined with an implementation, that implementation determines the value that is read from the property.

You do not have to use the property’s default memory to store the property value. You can use any other accessible data, such as a data member, as storage to store property values. If you do not write a value to *property-name* within *set-logic*, the property’s default memory retains whatever value it had prior to any operation that writes to the property.

This is the syntax for a SET accessor **without** an implementation:

**Syntax**

```
SET.
```

Without an implementation, any operation that writes the property writes the value directly to the property’s default memory without passing through *parameter-name*.

If the property is an array, the default accessor implementation handles the subscript references automatically. Providing an *array-index-parameter* in this case is a compiler error.

**Note:** This is equivalent to, but more efficient than, using an implementation to explicitly assign *property-name* the value of *parameter-name*.

**Examples**

The examples that follow show two different ways to access the same private data of a class using properties.
The first example, shows a class (r-DefineProperties1) that defines a PUBLIC property (cCurrentSalesRepName) followed by a procedure that accesses this property. The property is defined with two accessors without implementations, providing direct access to the property value. The GET accessor is PUBLIC, but the SET accessor is PRIVATE, allowing only the class to set the property value. In this case, the class sets the property from data (RepName field) in the sports2000 database provided by a buffer (bSalesRep), which is PRIVATE.

The class also provides a PUBLIC method (getNextSalesRep( )) to read the SalesRep table one record at a time and set the cCurrentSalesRepName property to the value of the RepName field for each record. This PUBLIC method also uses a PRIVATE method (restartSalesRep( )) to reset the record position to the beginning of the table, based on an INPUT parameter. The class constructor also uses this PRIVATE method to initialize the record buffer to the first record in the table. The class sets the cCurrentSalesRepName property to the Unknown value (?) if the SalesRep table is empty or getNextSalesRep( ) reaches the end of the SalesRep table.

```
CLASS r-DefineProperties1:

  DEFINE PUBLIC PROPERTY cCurrentSalesRepName AS CHARACTER NO-UNDO GET.
  PRIVATE SET.
  DEFINE PRIVATE BUFFER bSalesRep FOR SalesRep.

  CONSTRUCTOR PUBLIC r-DefineProperties1 ():
    restartSalesRep() NO-ERROR.
    IF ERROR-STATUS:ERROR THEN RETURN ERROR ERROR-STATUS:GET-MESSAGE(1).
  END CONSTRUCTOR.

  METHOD PRIVATE VOID restartSalesRep ():
    FIND FIRST bSalesRep NO-ERROR.
    IF NOT AVAILABLE bSalesRep THEN:
      cCurrentSalesRepName = ?.
      RETURN ERROR "SalesRep table empty".
    END.
    ELSE
      cCurrentSalesRepName = bSalesRep.RepName.
    END METHOD.

  METHOD PUBLIC VOID getNextSalesRep (INPUT lRestart AS LOGICAL):
    IF lRestart THEN DO:
      restartSalesRep() NO-ERROR.
      IF NOT AVAILABLE bSalesRep THEN
        RETURN ERROR ERROR-STATUS:GET-MESSAGE (1).
    END.
    ELSE DO:
      FIND NEXT bSalesRep NO-ERROR.
      IF NOT AVAILABLE bSalesRep THEN
        cCurrentSalesRepName = ?.
      ELSE
        cCurrentSalesRepName = bSalesRep.RepName.
      END.
    END.
  END METHOD.

END CLASS.
```
The following procedure (r-runDefineProperties1.p) instantiates the r-DefineProperties1 class, referenced by clProps, and reads and displays the value of the clProps:cCurrentSalesRepName property in a message, starting with the first SalesRep record found as part of class instantiation. The procedure then displays the value of clProps:cCurrentSalesRepName in a message for each record found by the clProps:getNextSalesRep( ) method, restarting from the beginning of the SalesRep table at the direction of the user.

**r-runDefineProperties1.p**

```plaintext
DEFINE VARIABLE clProps AS CLASS r-DefineProperties1 NO-UNDO.

clProps = NEW r-DefineProperties1() NO-ERROR.
IF ERROR-STATUS:ERROR THEN DO:
  MESSAGE ERROR-STATUS:GET-MESSAGE(1) VIEW-AS ALERT-BOX.
  QUIT.
END.

DO WHILE NOT clProps:cCurrentSalesRepName = ?:
  MESSAGE "The current sales rep is "
  clProps:cCurrentSalesRepName + ". Continue?"
  VIEW-AS ALERT-BOX QUESTION BUTTONS YES-NO UPDATE lContinue AS LOGICAL.
  IF NOT lContinue THEN LEAVE.
ELSE DO:
  clProps:getNextSalesRep(FALSE).
  IF clProps:cCurrentSalesRepName = ? THEN DO:
    MESSAGE "End of sales rep list. Restart?"
    VIEW-AS ALERT-BOX QUESTION BUTTONS YES-NO
    UPDATE lRestart AS LOGICAL.
    IF lRestart THEN
      clProps:getNextSalesRep(TRUE).
  END.
END.
END.
```

In the next example, the r-DefineProperties2 class defines a PUBLIC property (cNextSalesRepName) that provides the same data as the cCurrentSalesRepName property defined by the r-DefineProperties1 class. However, the GET accessor of the cNextSalesRepName property is also used to provide the same access to the SalesRep table that the getNextSalesRep( ) method provides for the r-DefineProperties1 class. So, the value of cNextSalesRepName changes with each access.
Because this cNextSalesRepName property incorporates the record access provided by the getNextSalesRep( ) method, the following procedure that accesses the cNextSalesRepName property must also use the property in a manner similar to how the r-runDefineProperties1.p procedure uses the getNextSalesRep( ) method. As a result, the class also provides a second, publicly writable property (lSalesRepRestart) to indicate when the reading of SalesRep records must restart from the beginning of the table. (Note that the getNextSalesRep( ) method provides its own INPUT parameter to indicate whether to restart record reading.)

Finally, the r-DefineProperties2 class constructor sets lSalesRepRestart together with an initial read of the cNextSalesRepName property in order to initialize the record buffer to the first record of the table and pass the associated RepName field value to the instantiating procedure as an OUTPUT parameter.
Thus, the following procedure (r-runDefineProperties2.p) instantiates the r-DefineProperties2 class, referenced by clProps, and reads and displays the data from the clProps:cNextSalesRepName property in a manner similar to how the r-runDefineProperties1.p procedure reads and displays the same data using the getNextSalesRep( ) method. However, because the clProps:cNextSalesRepName property always returns the RepName field for the next SalesRep record in the table, the r-runDefineProperties2.p procedure must provide a separate variable (cCurrentSalesRepName) of its own, which provides the same function that the cCurrentSalesRepName property provides for the r-DefineProperties1 class, which is to maintain a current value read from the RepName field.

r-runDefineProperties2.p

```
DEFINE VARIABLE clProps  AS CLASS r-DefineProperties2 NO-UNDO.
DEFINE VARIABLE cCurrentSalesRepName AS CHARACTER NO-UNDO.

clProps = NEW r-DefineProperties2(OUTPUT cCurrentSalesRepName) NO-ERROR.

DO WHILE NOT cCurrentSalesRepName = ?:
   MESSAGE "The current sales rep is " cCurrentSalesRepName + ". Continue?"
   VIEW-AS ALERT-BOX QUESTION BUTTONS YES-NO
   UPDATE lContinue AS LOGICAL.
   IF NOT lContinue THEN LEAVE.
   ELSE DO:
      cCurrentSalesRepName = clProps:cNextSalesRepName.
      IF cCurrentSalesRepName = ? THEN DO:
         MESSAGE "End of sales rep list. Restart?"
         VIEW-AS ALERT-BOX QUESTION BUTTONS YES-NO
         UPDATE lRestart AS LOGICAL.
         IF lRestart THEN
            ASSIGN clProps:lSalesRepRestart = TRUE
            cCurrentSalesRepName = clProps:cNextSalesRepName.
         END.
      END.
   END.
END.
```

Thus, the logic of the r-runDefineProperties2.p procedure is almost identical to the r-runDefineProperties1.p procedure, reading a clProps:cNextSalesRepName property instead of invoking a clProps:getNextSalesRep( ) method in order to read an appropriate value from the SalesRep table.

For more examples of property definitions, including static and abstract properties, see the descriptions of r-CustObj.cls, r-CustObjStatic.cls, and r-CustObjAbstract.cls in the CLASS statement reference entry.

Notes

- You cannot define a property within a procedure (internal or external) or within a method of a class (constructor or destructor). It can only be defined as a member of a class or as a prototype in an interface. For more information about declaring property prototypes in an interface, see the INTERFACE statement reference entry.
- PUBLIC and PROTECTED properties defined within a class definition (.cls) file maintain their characteristics throughout the inherited class hierarchy. Thus, you cannot shadow (override) properties in a subclass that are defined in a super class.
- You must define at least one GET or SET accessor, or define both accessors, for the property to be valid.
• You never invoke the GET and SET accessors defined for a property directly. These methods are only invoked implicitly when you read (GET) or write (SET) the value of the property. For example, you can read or write the property by using the property in an Assignment (\(=\)) statement or by passing the property as a parameter to a method, procedure, or user-defined function. For information on reading and writing property values, see the Class-based property access reference entry. As an alternative, you can define a method in a class to read or write the value of a data member that you separately define in the same class.

• If the property name is an ABL reserved keyword, you might need to use the THIS-OBJECT system reference or Type-name syntax to reference the property. For more information on referencing properties, see the reference entry for Class-based property access.

• To avoid any unexpected performance impact when using the property, ensure that the body of any GET or SET accessor minimizes processing that might incur delay when referencing the property.

• You cannot specify formatting information in a property definition. You can control property formatting using the same default rules for formatting a variable or data member:
  a) Rely on the default formatting for the data type of the property. For more information, see the Data types reference entry.
  b) Add formatting information when you access the property in a statement (for example, using a DISPLAY statement).

• You can handle application errors in an a property accessor as in any ABL block. By executing a RETURN ERROR action at the block level or a THROW action at the block level with the presence of a ROUTINE-LEVEL ON ERROR UNDO, THROW statement, the AVM returns the ERROR condition to the statement that references the property and works much like an error raised by a method. If a RETURN ERROR also includes the option to return a character string value, or you set the ReturnValue property of a Progress.Lang.AppError object that you THROW, you can get this value using the RETURN-VALUE function following the statement that references the property or in a CATCH block that catches the Progress.Lang.AppError object. If the body of an accessor contains an UNDO block, any unhandled ERROR condition in that block undoes only the data within that block, according to the NO-UNDO setting of the data. The property value, itself, is not undone unless the property is defined without NO-UNDO. For more information, see OpenEdge Development: Object-oriented Programming.

• If ERROR is raised during execution of an Assignment (\(=\)) statement, the value on the left-hand side usually remains unchanged from its value prior to the assignment. However, if the left-hand side of the assignment is a property and its SET accessor invokes the RETURN ERROR statement (raising ERROR on the assignment), the value of the property can be changed. This is because the SET accessor is a method, and like all methods that raise ERROR, any data elements that the SET accessor changes retain their most recent values after ERROR is raised. Thus, if the SET accessor changes the property value before invoking RETURN ERROR, the property retains its most recent change in value after ERROR is raised on the assignment.

• If an ABL property that implements a property defined in a .NET interface is accessed from .NET and it raises ERROR out of the accessor block, ABL returns a .NET System.Exception to the caller. If the error is raised by executing a RETURN ERROR
with the optional error string, the Message property of the System.Exception describes the
operation where the error occurred, but the error string is available only to the ABL
session, using the RETURN-VALUE function. If the error is raised by executing a
RETURN ERROR with an optional ABL error object or by executing an UNDO,
THROW, the System.Exception Message property includes both a description of the
operation where the error occurred and any messages from the ABL error object. If the
error is fatal, the AVM responds as for any ABL class, generating a protrace file and
exiting the session.

statement, DISPLAY statement, METHOD statement, RETURN statement

DEFINE QUERY statement

Defines a query that is created at compile time for use in one or more procedures, or within a
single class or class hierarchy. A query can be opened with an OPEN QUERY statement, and
records can be retrieved using a GET statement, BROWSE widget, or the FILL( ) method on a
ProDataSet object handle.

Syntax

```
DEFINE { [ [ NEW ] SHARED ] | [ PRIVATE | PROTECTED ] [ STATIC ] } QUERY query
FOR buffer-name [ field-list ] [ , buffer-name [ field-list ] ] ... [ CACHE n ]
[ SCROLLING ] [ RCODE-INFORMATION ]
```

NEW SHARED QUERY query

Defines and identifies a query to be shared with one or more procedures called directly or
indirectly by the current procedure. The called procedures must define the same query
name as SHARED. For shared queries, each buffer-name must be the name of a shared
buffer. The shared buffers must be specified in the same order both across shared queries
and in the OPEN QUERY.

SHARED QUERY query

Defines and identifies a query that was initially defined by another procedure as NEW
SHARED. For shared queries, each buffer-name must be the name of a shared buffer. The
shared buffers must be specified in the same order across shared queries and in the OPEN
QUERY.

[ PRIVATE | PROTECTED ] [ STATIC ] QUERY query

Defines and identifies a query as a data member of a class, and optionally specifies an
access mode (PRIVATE or PROTECTED) and scope (instance or STATIC) for that data
member. You cannot specify these options when defining a query as a data element of a
method (including constructors, destructors, and property accessors) or a procedure. For a
data member query, each buffer-name must be the name of a compatible data member
buffer (see the FOR option).
Note: The specified options are applicable only when defining a data member for a class in a class definition (.cls) file. Note also that you cannot shadow (override) the definition of a given query data member in a class hierarchy.

PRIVATE query data members can be accessed only by the defining class. PROTECTED query data members can be accessed by the defining class and any of its derived classes. The default access mode is PRIVATE. When you reference a query from another data member definition (such as a data-source) defined in the same class or class hierarchy, the access mode of the query cannot be more restrictive than the access mode of the referencing data member.

A query defined with the STATIC option is a static data member of the class type for which it is defined and is scoped to the ABL session where it is referenced. ABL creates one copy of the specified class static query on first reference to the class type, and ABL creates only one such copy for any number of instances of the class that you create. You can directly reference an accessible static query data member from any other static or instance class member defined in the same class or class hierarchy.

Without the STATIC option, ABL creates an instance query data member that is scoped to a single instance of the class where it is defined. ABL creates one copy of the specified instance query for each such class instance that you create. You cannot directly reference an instance query data member from a STATIC class member definition defined within the same class or class hierarchy.

For more information on accessing queries of different access modes and scopes, see the reference entry for Class-based data member access.

Note: Members of a class are grouped into six namespaces, including buffers/temp-tables, methods, variables/properties/events, ProDataSets, queries, and data-sources. Queries defined as members of a class share the same namespace. There can be only one class member in this namespace with a given name.

For more information on where and how to define data members in a class, see the CLASS statement reference entry.

QUERY query

Defines and identifies a query whose records you can access only within the current procedure, method of a class (including constructors, destructors, and property accessors), or as a PRIVATE data member of a class.

FOR buffer-name [ field-list ] [ , buffer-name [ field-list ] ] ... 

Specifies the buffers to be used by the query, where buffer-name is a table or alternate buffer name. For a shared query, each buffer-name must be a shared buffer. If the query is a data member of a class, you must specify the name of a compatible buffer. Thus, if the query is a static data member, the buffer must also be a static data member; if the query is PROTECTED, the buffer must also be defined as PROTECTED or inherited from a super class; and if the data-source is PRIVATE, the buffer can be defined as either PRIVATE or PROTECTED. If the query is a PRIVATE instance data member, you can also specify a default database table buffer; you cannot specify a default database buffer for a query data member defined with any other combination of access mode and scope.
**Note:** ABL defines the default buffer for every database table that you access in a class as a PRIVATE instance buffer data member.

If the query definition references more than one buffer, it defines a join.

Once the query has been defined, you cannot change the buffers that it references, even if the query is closed and re-opened. For example, a buffer, buff1, is created for the Customer table in a DEFINE QUERY or OPEN QUERY for the query, qry1. The query is run and closed. You cannot now DEFINE or OPEN qry1 with buff1 for the item table. You can reuse buffers with CREATE QUERY, but you must re-run QUERY-PREPARE.

The *field-list* specifies a list of fields to include or exclude when you open the query. This is the syntax for *field-list*:

```
{  
FIELDS [ ( [ field ... ] ) ]  
| EXCEPT [ ( [ field ... ] ) ]  
}
```

The FIELDS option specifies the fields you want to include in the query, and the EXCEPT option specifies the fields that you want to exclude from the query. The *field* parameter is the name of a single field in the table specified by *buffer-name*. If *field* is an array reference, the whole array is retrieved even if only one element is specified. Specifying FIELDS with no *field* references causes the AVM to retrieve sufficient information to extract the ROWID value for each record in the query (returnable using the ROWID function). Specifying EXCEPT with no *field* references or specifying *buffer-name* without a *field-list* causes the AVM to retrieve all fields for each record in the query.

**Note:** The AVM ignores the FIELDS option for temp-tables.

This statement defines a query to retrieve only the name and balance fields from the Customer table:

```
DEFINE QUERY custq FOR Customer FIELDS (name balance).
```

This statement defines a query to retrieve all fields of the Customer table except the name and balance fields:

```
DEFINE QUERY custq FOR Customer EXCEPT (name balance).
```

When you specify a field list for a query, the AVM might retrieve additional fields or complete records depending on the type of query operation and the DataServer that provides the records. Thus, the AVM:

- Retrieves any additional fields required by the client to complete the record selection.
**DEFINE QUERY statement**

- Retrieves complete records when you open the query with EXCLUSIVE-LOCK or update any row (such as with a browse). This ensures proper operation of updates and the local before-image (BI) file. For information on the local BI file, see *OpenEdge Data Management: Database Administration*.

- Retrieves complete records for DataServers that do not support SHARE-LOCK. For more information, see the OpenEdge DataServer Guides (OpenEdge Data Management: DataServer for Microsoft SQL Server, OpenEdge Data Management: DataServer for ODBC, and OpenEdge Data Management: DataServer for Oracle).

**Note:** Always specify fields that you plan to reference in the field list. Only those extra fields that the client requires for record selection are added to the specified field list. The AVM distributes record selection between the client and server depending on a number of factors that change with each OpenEdge release. Therefore, never rely on fields that you did not specify but which the AVM fetches for its own needs; they might not always be available. There is no additional cost to specify a field in the list that you otherwise expect the AVM to provide.

This query example retrieves the Customer.CustNum field in addition to those specified in the field lists because it is required to satisfy the inner join between the Customer and Order tables:

```
r-qryjoin.p
```

```define query coq for customer fields(name),
    order fields(ordernum salesrep).
id open query coq for each customer, each order of customer.
repeat:
    get next coq.
    if not available order then leave.
    display customer.name customer.custnum order.ordernum order.salesrep
        with frame q-frame 10 down.
end.
```  

However, do not rely on the AVM to always provide such extra fields. For reliability, add the CustNum field to the Customer field list. For example:

```define query coq for customer fields(name custnum),
    order fields(ordernum salesrep).
```

When you specify a field list in a shared query, you must specify the complete field list in the NEW SHARED query definition. Each corresponding SHARED query definition in another procedure file (.p) requires only the FIELDS or EXCEPT keywords, but can also include empty parentheses or the complete field list with no difference in functionality.

You can match this NEW SHARED query definition for Customer with any of the following SHARED query definitions with no effective difference:
If you define a NEW SHARED query with a field list and a matching SHARED query without a field list, or if you define a NEW SHARED query without a field list and a matching SHARED query with a field list, the AVM raises the ERROR condition when you run the procedure file that contains the SHARED query.

CACHE $n$

Specifies the number of records of the query to hold in memory for a NO-LOCK query. Generally, caching more records produces better browse performance when accessing a database across a network. However, caching consumes both memory and CPU time for buffer management.

If you specify the CACHE option, the SCROLLING option is assumed. If a query is referenced in a DEFINE BROWSE statement, caching occurs by default. The default for a query involving only one table is 50 records. The default for a multi-table query is 30 records. If you specify CACHE 0 in the DEFINE QUERY statement, no caching occurs.

SCROLLING

Specifies that you can jump to a location within the list of records that satisfy the query by using the REPOSITION statement. If you do not use this option, you can only use the FIRST, NEXT, LAST, and PREV options of the GET statement to navigate within the list. Queries are faster if you do not use this option, but you must specify it to use the REPOSITION statement. For non-OpenEdge databases, if you do not specify SCROLLING, you can only move forward through the list of records using the FIRST and NEXT options of the GET statement.

RCODE-INFORMATION

Note: This option is the default behavior (thus, it has no effect). It is supported only for backward compatibility.

Examples

The following example defines two queries, q-salesrep and q-cust. The first is opened in the main procedure block and is used to find all SalesRep records. The q-cust query is used to find all Customers associated with a SalesRep. The results of the q-cust query are displayed in a browse widget. The q-cust query is reopened each time you find a new SalesRep.

/* main.p */
DEFINE NEW SHARED QUERY q FOR Customer FIELDS(CustNum Name).

/* shared.p's */
DEFINE SHARED QUERY q FOR Customer FIELDS.
DEFINE SHARED QUERY q FOR Customer EXCEPT.
DEFINE SHARED QUERY q FOR Customer FIELDS ( ).
DEFINE SHARED QUERY q FOR Customer FIELDS(CustNum Name).
The following example uses the RCODE-INFORMATION option of the DEFINE QUERY statement to extract index information from a compile-time defined query. If you run the example with the RCODE-INFORMATION option commented out, the AVM reports a run-time error.

```
r-defqry.p

DEFINE QUERY q-salesrep FOR SalesRep
  FIELDS(SalesRep RepName Region MonthQuota).
DEFINE QUERY q-cust FOR Customer
  FIELDS(CustNum Name Phone).

DEFINE BROWSE cust-brws QUERY q-cust
  DISPLAY Customer.CustNum Customer.Name Customer.Phone
  WITH 5 DOWN TITLE "Customer Information".

DEFINE BUTTON b_next LABEL "Next".
DEFINE BUTTON b_quit LABEL "Quit" AUTO-ENDKEY.

FORM
  WITH FRAME rep-info SIDE-LABELS TITLE "Sales Rep. Info".

FORM b_next space(5) b_quit
  WITH FRAME butt-frame COLUMN 60.

ON CHOOSE OF b_next DO:
  GET NEXT q-salesrep.
  IF NOT AVAILABLE SalesRep THEN GET FIRST q-salesrep.
  RUN disp-rep.
END.

OPEN QUERY q-salesrep FOR EACH SalesRep NO-LOCK.
GET FIRST q-salesrep.
RUN disp-rep.

ENABLE cust-brws WITH FRAME cust-info.
ENABLE ALL WITH FRAME butt-frame.

WAIT-FOR WINDOW-CLOSE OF CURRENT-WINDOW.

PROCEDURE disp-rep:
       SalesRep.MonthQuota
  WITH FRAME rep-info CENTERED SIDE-LABELS TITLE "Sales Rep. Info".
  OPEN QUERY q-cust FOR EACH Customer OF SalesRep NO-LOCK.
END PROCEDURE.
```

```
r-rcdinf.p

/* r-rcdinf.p */
/* Extracts index information from a compile-time defined query. */
DEFINE VARIABLE h AS HANDLE NO-UNDO.

DEFINE QUERY q FOR Customer RCODE-INFORMATION.

h = QUERY q:HANDEL.
OPEN QUERY q FOR EACH Customer BY Customer.Name.
MESSAGE h:INDEX-INFORMATION.
```
Notes

- You cannot define a SHARED or NEW SHARED query in a class definition (.cls) file. If you do, ABL generates a compilation error.

- A query can be compile-time defined (often referred to as a static query object), where the query is defined and created at compile time using this statement, or it can be run-time defined (often referred to as a dynamic query object), where the query is defined and created at run time using the CREATE QUERY statement and query object handle operations. A compile-time defined query can also be defined as a static data member of a class. In this case, it is a static query object that is also a class static data member.

- After you define a query, you must open it with the OPEN QUERY statement before you can fetch any records.

- A SHARED query remains in scope for an instance of a persistent procedure until the instance is deleted. This is true even if the original procedure that defined the query as NEW SHARED goes out of scope while the procedure instance remains persistent.

If a trigger or internal procedure of a persistent procedure executes an external subprocedure that defines a SHARED query, ABL includes the persistent procedure in the resolution of the corresponding NEW SHARED query as though the procedure were on the procedure call stack.

- Specifying a field list (field-list) for buffer-name can increase the performance of remote (network) queries substantially over specifying buffer-name alone.

- If you reference an unfetched database field in a query at run time, the AVM raises the ERROR condition. ABL does not perform a compile-time check to ensure that the field is fetched because the compiler cannot reliably determine how a particular record will be read (that is, whether it is retrieved using a FIND statement, retrieved with or without a field list, including additional fields to satisfy join conditions, etc.).

- Unlike with block record retrieval operations that include record updates and deletes (FOR EACH, etc.), field lists generally enhance query performance even for queries whose rows you plan to update. Queries generate complete result lists, with or without field lists, before any updates to individual rows are applied.

- You can specify the Field List Disable (-fldisab1e) startup parameter to cancel field list retrieval and force the AVM to retrieve complete records. This is a run-time client session parameter that is especially useful for deployed applications whose database triggers are later redefined to reference unfetched fields (raising the ERROR condition). Using -fldisab1e provides a workaround that allows the application to run (although more slowly) until the application can be fixed.

- You cannot specify field lists in an OPEN QUERY statement.

- In a shared query, the shared buffers must be specified in the same order across all the shared queries and in the OPEN QUERY statement.

- A ProDataSet data-relation defined with REPOSITION or SELECTION is overridden if a query is defined for a child relation data-source. Normally, if REPOSITION is not specified, the child query selects the children of the parent. But coding a query for the child
DEFINE RECTANGLE statement

Defines a rectangle widget that is created at compile time for use within a single procedure or class.

Note: Does not apply to SpeedScript programming.

Syntax

```
DEFINE [PRIVATE] RECTANGLE rectangle [LIKE rectangle2 ]
  [NO-FILL ]
  [ { EDGE-CHARS width } | { EDGE-PIXELS width } ]
  [DCOLOR expression ]
  [BCOLOR expression ]
  [FGCOLOR expression ]
  [GRAPHIC-EDGE ]
  [PFCOLOR expression ]
  [ROUNDED ]
  [GROUP-BOX ]
  [size-phrase ]
  [TOOLTIP tooltip ]
  { [trigger-phrase ] }
```

PRIVATE RECTANGLE rectangle

Defines and identifies a rectangle widget as a class-scoped object. A class-scoped handle-based object is not a member of a class, but provides a resource that is privately available to the class definition similar to a non-shared data element in a procedure definition. The option to specify the PRIVATE access mode is provided for readability. You cannot specify PRIVATE when defining a rectangle widget as a data element in a method or procedure.

Note: This option is applicable only when defining a class-scoped rectangle widget in a class definition (.cls) file.

RECTANGLE rectangle

Defines and identifies a rectangle widget for access only within the current procedure, class, or method of a class.

See also
Class-based data member access, CLOSE QUERY statement, CREATE QUERY statement, CURRENT-RESULT-ROW function, DEFINE BROWSE statement, DEFINE DATASET statement, GET statement, NUM-RESULTS function, OPEN QUERY statement, REPOSITION statement, RUN statement
LIKE rectangle2

Specifies a previously defined rectangle whose characteristics you want to apply to the new rectangle. If you name a rectangle with this option, you must have defined that rectangle previously in the procedure.

NO-FILL

Indicates that only the outline of the rectangle should be drawn. By default, the rectangle is filled with the background color.

EDGE-CHARS width

Specifies the width of the rectangle outline in characters. The default width is 1. If you do not want an edge on the rectangle, specify EDGE-CHARS 0.

EDGE-PIXELS width

Specifies the width of the rectangle outline in pixels. The default width is 1. If you do not want an edge on the rectangle, specify EDGE-PIXELS 0.

DCOLOR expression

Specifies the fill color of the rectangle in character interfaces. This option is ignored in graphical interfaces.

BGCOLOR expression

Specifies the background color or fill color of the rectangle in graphical interfaces. This option is ignored in character interfaces.

FGCOLOR expression

Specifies the foreground color or edge color of the rectangle in graphical interfaces. This option is ignored in character interfaces.

GRAPHIC-EDGE

Specifies that in a character interface, the rectangle is drawn with graphic characters. This option is ignored in a graphical interface. This overrides the EDGE-CHARS and EDGE-PIXELS options. The border is one graphic unit thick.

PFCOLOR expression

Specifies the edge color of the rectangle in character interfaces. This option is ignored in graphical interfaces. It is also ignored if you specify GRAPHIC-EDGE.

ROUNDED

Specifies that the rectangle appears with rounded corners (whether the display is set to the Windows XP Theme or the Windows Classic Theme).

This option is ignored in character interfaces.

GROUP-BOX

Specifies the rectangle as a group box, which surrounds one or more user interface widgets to visually indicate a relationship among the widgets. The appearance of a group box changes automatically to conform to the current display setting. When the display is set to
the Windows XP Theme, the group box rectangle appears with rounded corners and a single-line border. When the display is set to the Windows Classic Theme, the group box appears with square corners and a shaded double-line border.

This option is ignored in character interfaces.

**size-phrase**

Specifies the outside dimensions of the rectangle widget. This is the syntax for *size-phrase*:

\[
\{ \text{SIZE} \mid \text{SIZE-CHARS} \mid \text{SIZE-PIXELS} \} \ \text{width BY height}
\]

If you specify SIZE or SIZE-CHARS, the units are characters; if you specify SIZE-PIXELS, the units are pixels. For character units, the values *width* and *height* must be decimal constants. For pixels units, they must be integer constants. For more information, see the SIZE phrase reference entry.

**TOOLTIP** *tooltip*

Allows you to define a help text message for a rectangle widget. The AVM automatically displays this text when the user pauses the mouse button over the rectangle widget.

You can add or change the TOOLTIP option at any time. If TOOLTIP is set to "" or the Unknown value (?), then the ToolTip is removed. No ToolTip is the default. The TOOLTIP option is supported in Windows only.

**trigger-phrase**

Specifies application triggers for the rectangle.

For more information, see the Trigger phrase reference entry.

**Example**

The following example uses a set of thin rectangles as lines to create graphic columns within a frame background:
DEFINE VARIABLE item-tot AS DECIMAL NO-UNDO LABEL "Value".

DEFINE RECTANGLE vline1 SIZE .4 BY 5 EDGE-PIXELS 2.
DEFINE RECTANGLE vline2 LIKE vline1.
DEFINE RECTANGLE vline3 LIKE vline1.
DEFINE RECTANGLE vline4 LIKE vline1.
DEFINE RECTANGLE vline5 LIKE vline1.
DEFINE RECTANGLE vline6 LIKE vline1.
DEFINE RECTANGLE hline SIZE 78 BY .1 EDGE-PIXELS 2.

DEFINE FRAME item-info
   Item.ItemNum
   Item.ItemName
   Item.OnHand
   Item.ReOrder
   Item.OnOrder
   Item.Price
   item-tot
ENDFRAME
BACKGROUND SKIP(1) hline
   vline1 AT 9
   vline2 AT 25
   vline3 AT 33
   vline4 AT 42
   vline5 AT 51
   vline6 AT 65
WITH TITLE "Inventory Current Value" CENTERED USE-TEXT 5 DOWN.

FOR EACH Item NO-LOCK WITH FRAME item-info:
   DISPLAY
      Item.ItemNum
      Item.ItemName
      Item.OnHand
      Item.ReOrder
      Item.OnOrder
      Item.Price
      Item.OnHand * Item.Price @ item-tot.

Notes

- To create the compile-time defined rectangle you are defining, you must define a compile-time defined frame that contains the rectangle. Each frame you define that contains the same rectangle creates an additional instance of that rectangle. The handle for a compile-time defined rectangle is not available until the rectangle is created.

- You can specify an application-defined widget ID for a compile-time defined rectangle widget using the form-item phrase in either the FORM statement or the DEFINE FRAME statement. See the FORM statement and DEFINE FRAME statement reference entries for more information.

- When defining a rectangle, you must specify either the LIKE option or the size phrase.

See also  
Class-based data member access, FORM statement
DEFINE STREAM statement

Defines a stream for use in one or more procedures, or within a single class. Use this statement when you want to use streams other than the two ABL built-in unnamed streams. Using additional streams allows you to get input from more than one source simultaneously or to send output to more than one destination simultaneously.

Syntax

\[
\text{DEFINE} \ \{ \ [ \ \text{NEW} \ [ \ \text{GLOBAL} \ ] \ ] \ \text{SHARED} \ | \ [ \ \text{PRIVATE} \ ] \ \} \ \text{STREAM} \ \text{stream-name}
\]

NEW SHARED STREAM \textit{stream-name}

Defines and identifies a stream that can be shared by other procedures. When the procedure using the DEFINE NEW SHARED STREAM statement ends, the stream is no longer available to any procedure.

NEW GLOBAL SHARED STREAM \textit{stream-name}

Defines and identifies a stream that can be shared by other procedures and that will remain available even after the procedure that contains the DEFINE NEW GLOBAL SHARED STREAM statement ends.

SHARED STREAM \textit{stream-name}

Defines and identifies a stream that was created by another procedure using the DEFINE NEW SHARED STREAM statement or the DEFINE NEW GLOBAL SHARED STREAM statement.

[ PRIVATE ] STREAM \textit{stream-name}

Defines and identifies a stream as a class-scoped object. A class-scoped handle-based object is not a member of a class, but provides a resource that is privately available to the class definition similar to a non-shared data element in a procedure definition. The option to specify the PRIVATE access mode is provided for readability. You cannot specify PRIVATE when defining a stream as a data element in a method or procedure.

\textbf{Note:} This option is applicable only when defining a class-scoped stream in a class definition (.cls) file.

STREAM \textit{stream-name}

Defines and identifies a stream for access only within the current procedure, class, or method of a class.

Examples

This procedure, in a single pass through the item table, uses the rpt stream to create a report and the exceptions stream to create a list of exceptions:
Include the DISPLAY statement in the `r-dfstr2.p` procedure in the `r-dfstr.p` procedure for efficiency. (It is in a separate procedure here to illustrate shared streams.)

### Notes

- You cannot define a SHARED or NEW SHARED stream in a user-defined function, an internal procedure, or a persistent procedure. If you do, the AVM raises an ERROR on the RUN statement that creates the procedure.

- You cannot define a SHARED or NEW SHARED stream in a class definition (.cls) file. If you do, ABL generates a compilation error.

- You can overcome the limitations on SHARED or NEW SHARED streams by using stream handles. For more information, see the Stream object handle reference entry and the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces.

- ABL automatically provides two unnamed streams to each procedure: the input stream and the output stream. These streams give the procedure a way to communicate with an input source and an output destination. For example, the following statement tells ABL to use the unnamed input stream to get input from the file named `testfile`:

```plaintext
DEFINE VARIABLE fnr AS CHARACTER NO-UNDO FORMAT "x(12)".
DEFINE VARIABLE fne AS CHARACTER NO-UNDO FORMAT "x(12)".
DEFINE VARIABLE excount AS INTEGER NO-UNDO
LABEL "Total Number of exceptions".
DEFINE NEW SHARED BUFFER xitem FOR item.
DEFINE NEW SHARED STREAM rpt.
DEFINE STREAM exceptions.
SET fnr LABEL "Enter filename for report output" SKIP(1)
fne LABEL "Enter filename for exception output"
WITH SIDE-LABELS FRAME fnames.
OUTPUT STREAM rpt TO VALUE(fnr) PAGED.
OUTPUT STREAM exceptions TO VALUE(fne) PAGED.
FOR EACH xitem:
  IF on-hand < alloc THEN DO:
    DISPLAY STREAM exceptions
    xitem.ItemNum xitem.ItemName xitem.OnHand xitem.Allocated
    WITH FRAME xitem DOWN.
    excount = excount + 1.
  END.
RUN r-dfstr2.p.
END.
DISPLAY STREAM exceptions SKIP(1) excount WITH FRAME exc SIDE-LABELS.
DISPLAY STREAM rpt WITH FRAME exc.
OUTPUT STREAM rpt CLOSE.
OUTPUT STREAM exceptions CLOSE.
```
- Using the DEFINE STREAM statement creates a stream, but it does not actually open that stream. To open a stream, you must use the STREAM option with the INPUT FROM, INPUT THROUGH, OUTPUT TO, OUTPUT THROUGH, or INPUT-OUTPUT THROUGH statements. You must also use the STREAM option with any data handling statements that move data to and from the stream.

- After you open the stream, you can use the SEEK function to return the offset value of the file pointer, or you can use the SEEK statement to position the file pointer to any location in the file.

- For information about limits on the number of streams per procedure, see the application limits appendix in *OpenEdge Deployment: Managing ABL Applications*.

---

**DEFINE SUB-MENU statement**

Defines a submenu widget that is created at compile time for use within a single procedure or class. You can use a submenu widget as a pull-down menu within a menu bar or as a submenu of a pull-down menu or pop-up menu.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```plaintext
DEFINE [ PRIVATE ] SUB-MENU submenu
    [ BGCOLOR expression ]
    [ DCOLOR expression ]
    [ FGCOLOR expression ]
    [ PFCOLOR expression ]
    [ FONT number ]
    [ SUB-MENU-HELP ]
    { LIKE menu | menu-element-descriptor ... }

[ PRIVATE ] SUB-MENU submenu
```

Defines and identifies a submenu widget as a class-scoped object. A class-scoped handle-based object is not a member of a class, but provides a resource that is privately available to the class definition similar to a non-shared data element in a procedure definition. The option to specify the PRIVATE access mode is provided for readability. You cannot specify PRIVATE when defining a submenu widget as a data element in a method or procedure.
Note: This option is applicable only when defining a class-scoped sub-menu widget in a class definition (.cls) file.

SUB-MENU submenu

Defines and identifies a submenu for access only within the current procedure, class, or method of a class.

BGCOLOR expression

Specifies the background color for the submenu in graphical interfaces. This option is ignored in character interfaces and Windows.

DCOLOR expression

Specifies the display color for the submenu in character interfaces. This option is ignored in graphical interfaces.

FGCOLOR expression

Specifies the foreground color for the submenu in graphical interfaces. This option is ignored in character interfaces.

PFCOLOR expression

Specifies the prompt-for color for the submenu in character interfaces. This option is ignored in graphical interfaces.

FONT number

Has no effect; supported only for backward compatibility.

SUB-MENU-HELP

Has no effect; supported only for backward compatibility.

LIKE menu

Specifies a previously defined menu or submenu whose characteristics you want to apply to the new submenu. If you name a menu with this option, you must have previously defined that menu in the procedure. If you name a submenu with this option, that submenu must have already been used as part of a menu definition.

menu-element-descriptor

Specifies an element displayed on the menu. Each element is either a choosable menu item, a submenu, non-choosable text, a rule, or a blank space. You must specify one or more menu elements, unless you use the LIKE option.

This is the syntax for menu-element-descriptor:
DEFINE SUB-MENU statement

\{
  RULE
  SKIP
  SUB-MENU submenu [ DISABLED ] [ LABEL label ]
  menu-item-phrase
\}

RULE

Specifies that a rule or line is inserted at this point in the submenu. You can use this, for example, to divide the submenu into sections.

SKIP

Specifies that a blank line is inserted at this point in the submenu. You can use this, for example, to divide the submenu into sections.

SUB-MENU submenu [ DISABLED ] [ LABEL label ]

Specifies that a submenu is displayed at this menu item. The submenu must be previously defined in the procedure. The submenu appears when the user chooses that item. The submenu cannot be a menu bar. The DISABLED and LABEL options for a submenu are the same as described for the menu-item-phrase.

menu-item-phrase

Specifies a choosable menu item. This is the syntax for menu-item-phrase:

\{\n  MENU-ITEM menu-item-name
    [ ACCELERATOR keylabel ]
    [ BGCOLOR expression ]
    [ DCOLOR expression ]
    [ DISABLED ]
    [ FGCOLOR expression ]
    [ FONT expression ]
    [ LABEL label ]
    [ PFCOLOR expression ]
    [ READ-ONLY ]
    [ TOGGLE-BOX ]
  \}

MENU-ITEM menu-item-name

The name of the menu item you are defining.

ACCELERATOR keylabel

Specifies a keyboard accelerator for this menu item. A keyboard accelerator is a key—possibly modified by SHIFT, CONTROL, or ALT—that chooses a menu item even if the menu is not displayed. The value keylabel must be a character-string expression that evaluates to a valid key label recognized by the AVM, such as a, F1, or ALT+SHIFT+F1. See
the chapter on handling user input in the *OpenEdge Development: Programming Interfaces* for the precedence rules that the AVM uses for handling keyboard input.

**BGCOLOR expression**

Specifies the background color for the menu item in graphical interfaces. If you omit this option, the menu item inherits the background color of the submenu.

**DCOLOR expression**

Specifies the display color for the menu item in character interfaces. If you omit this option, the menu item inherits the display color of the submenu.

**DISABLED**

Specifies that the menu item is initially disabled for input. This means that the user cannot choose this item. Disabled items are grayed out in environments that support it.

**FGCOLOR expression**

Specifies the foreground color for the menu item in graphical interfaces. If you omit this option, the menu item inherits the foreground color of the submenu.

**FONT expression**

Specifies the font for the menu item. If you omit this option, the menu item inherits the font of the menu.

**LABEL label**

Specifies the text that displays in the submenu for a choosable menu item or submenu. If you omit LABEL, the AVM displays the item handle by default.

You can include an ampersand (&) within the label to indicate that the following letter acts as a mnemonic for the menu item. This means that when the menu is displayed, the user can choose the item by pressing that single key. If you do not include an ampersand within the label, Windows treats the first character as a mnemonic. To include a literal ampersand within a label, specify a double ampersand (&&).

**PFCOLOR expression**

Specifies the prompt-for color for the menu item in character interfaces. If you omit this option, the menu item inherits the prompt-for color of the submenu.

**READ-ONLY**

Specifies that this menu item is read-only text. The user cannot choose this item.

**TOGGLE-BOX**

Specifies that the menu item is displayed as a checkbox that the user can toggle on or off. In environments that do not support this option, it is ignored.

**trigger-phrase**

Specifies application triggers for the menu item. Typically, you associate a CHOOSE trigger with each menu item.

For more information, see the *Trigger phrase* reference entry.
Example

The `r-menu.p` procedure defines three pull-down submenus. One of the submenus, `myedit`, contains a nested submenu, `myobjects`. The procedure defines a menu bar, `mybar`, that contains two submenus labelled `File` and `Edit`. The handle of `mybar` is assigned to a window `mywin`. The ON statements define triggers to execute when you choose the corresponding menu items.

```plaintext
DEFINE VARIABLE mywin AS HANDLE NO-UNDO.

DEFINE SUB-MENU myfile
  MENU-ITEM m1 LABEL "Save"
  MENU-ITEM m2 LABEL "Save As"
  MENU-ITEM m3 LABEL "Exit".

DEFINE SUB-MENU myobjects
  MENU-ITEM m1 LABEL "Circle"
  MENU-ITEM m2 LABEL "Line"
  MENU-ITEM m3 LABEL "Rectangle"
  MENU-ITEM m4 LABEL "Text".

DEFINE SUB-MENU myedit
  SUB-MENU myobjects LABEL "Add"
  MENU-ITEM e1 LABEL "Delete"
  MENU-ITEM e2 LABEL "Copy".

DEFINE MENU mybar MENUBAR
  SUB-MENU myfile LABEL "File"
  SUB-MENU myedit LABEL "Edit".

CREATE WINDOW mywin
  ASSIGN MENUBAR = MENU mybar:HANDLE.

DEFINE BUTTON b1 LABEL "Text Mode".
DEFINE BUTTON b2 LABEL "Graphics Mode".

CURRENT-WINDOW = mywin.
FORM
  b1 at X 10 Y 120
  b2 at X 120 Y 120
  WITH FRAME x.
  ENABLE b1 b2 WITH FRAME x.
ON CHOOSE OF b1 IN FRAME x DO:
  MENU-ITEM m1:SENSITIVE IN MENU myobjects = FALSE.
  MENU-ITEM m2:SENSITIVE IN MENU myobjects = FALSE.
  MENU-ITEM m3:SENSITIVE IN MENU myobjects = FALSE.
  MENU-ITEM m4:SENSITIVE IN MENU myobjects = TRUE.
END.

ON CHOOSE OF b2 IN FRAME x DO:
  MENU-ITEM m1:SENSITIVE IN MENU myobjects = TRUE.
  MENU-ITEM m2:SENSITIVE IN MENU myobjects = TRUE.
  MENU-ITEM m3:SENSITIVE IN MENU myobjects = TRUE.
  MENU-ITEM m4:SENSITIVE IN MENU myobjects = FALSE.
END.

WAIT-FOR CHOOSE OF MENU-ITEM m3 IN MENU myfile.
DELETE WIDGET mywin.
```

Notes

- To create the compile-time defined submenu you are defining, along with any of its descendents (submenus and menu items), you must define a compile-time defined menu that contains the submenu. Each menu you define that contains the same submenu creates an additional instance of the submenu and each of its descendents. The handles for a
compile-time defined submenu and its descendents are not available until the submenu is created in a menu.

- You cannot define a submenu with the same name more than once in the same menu tree. Thus, if menu mFile contains both submenu mOptions and submenu mSave, submenu mSave cannot also contain submenu mOptions.

- Menu items in different menus and submenus can have the same names. In the above procedure, the menu items in myfile and myobjects share the same names. To avoid ambiguity, use the IN MENU or IN SUB-MENU option to identify the parent menu or submenu.

- There are instances where you cannot avoid ambiguity in menu item references. In such instances, ABL always references the first unambiguous instance of the menu item. In particular, if the same submenu containing a menu item appears in more than one menu and each menu defines another instance of the same menu item, you can only reference that menu item in the submenu from the first menu that contains it. Thus, if submenu mOptions contains menu item mSave and the menus mFile and mDraw (in that order) both contain submenu mOptions and another menu item mSave, you can only reference menu item mSave in submenu mOptions from menu mFile. You cannot uniquely reference menu item mSave in submenu mOptions from menu mDraw because menu mDraw contains another menu item mSave.

- When a menu item is disabled, it appears grayed-out (if the environment supports that) and it cannot be chosen.

---

**DEFINE TEMP-TABLE statement**

Defines a temp-table that is created at compile time. The AVM stores temp-tables in memory (with potential overflow to disk). Among procedures, a temp-table can be either global (lasting for the entire ABL session) or local (lasting only as long as the procedure that creates it), and either shared (visible to other procedures that want to access it) or non-shared (visible just to the procedure that created it). In a class, a temp-table can be defined for use within a single class or class hierarchy.
DEFINE TEMP-TABLE statement

Syntax

```
DEFINE { [ NEW [ GLOBAL ] ] SHARED } |
  [ PRIVATE | PROTECTED | STATIC ] }
TEMP-TABLE temp-table-name [ NO-UNDO ]
[ NAMESPACE-URI namespace ] [ NAMESPACE-PREFIX prefix ]
[ XML-NODE-NAME node-name ] [ SERIALIZE-NAMESPACE serialize-name ]
[ REFERENCE-ONLY ]
[ LIKE table-name
  [ VALIDATE ]
  [ USE-INDEX index-name [ AS PRIMARY ] ] ... ]
[ LIKE-SEQUENTIAL table-name
  [ VALIDATE ]
  [ USE-INDEX index-name [ AS PRIMARY ] ] ... ]
[ RCODE-INFORMATION ]
[ BEFORE-TABLE before-table-name ]
FIELD field-name
  { AS data-type | LIKE field [ VALIDATE ] }
  [ field-options ]
] ... 
INDEX index-name
  [ [ AS | IS ] [ UNIQUE ] [ PRIMARY ] [ WORD-INDEX ] ]
  { index-field [ ASCENDING | DESCENDING ] } ... 
] ...
```

NEW SHARED TEMP-TABLE temp-table-name

Defines and identifies a temp-table object that can be shared by one or more procedures called directly or indirectly by the current procedure. The temp-table remains available to other procedures until the procedure that defined it ends. The called procedures must define the same temp-table name using a DEFINE SHARED TEMP-TABLE statement.

**Note:** A SHARED temp-table cannot have a BEFORE-TABLE.

NEW GLOBAL SHARED TEMP-TABLE temp-table-name

Defines and identifies a global shared temp-table object. The scope of a global shared temp-table is the ABL session. The first procedure to define a temp-table NEW GLOBAL SHARED establishes it. Subsequent procedures access it using a DEFINE SHARED TEMP-TABLE statement.

**Note:** ABL does not establish multiple global shared temp-tables with the same name in the same ABL session.

SHARED TEMP-TABLE temp-table-name

Defines and identifies a temp-table object that was initially defined by another procedure using a DEFINE NEW SHARED TEMP-TABLE or DEFINE NEW GLOBAL SHARED TEMP-TABLE statement.
The procedure that establishes the temp-table determines the name. The procedures that share the temp-table use that name to identify it.

\[
[ \text{PRIVATE} | \text{PROTECTED} ] [ \text{STATIC} ] \text{ TEMP-TABLE } temp-table-name
\]

Defines and identifies a temp-table object as a data member of a class, and optionally specifies an access mode (PRIVATE or PROTECTED) and scope (instance or STATIC) for that data member. You cannot specify any of these options for a temp-table in an interface definition (INTERFACE statement block) or when defining a temp-table as a data element of a procedure.

**Note:** The specified options are applicable only when defining a data member for a class in a class definition (.cls) file. Note also that you cannot shadow (override) the definition of a given temp-table data member in a class hierarchy.

PRIVATE temp-table data members can be accessed only by the defining class. PROTECTED temp-table data members can be accessed by the defining class and any of its derived classes. The default access mode is PRIVATE. When you reference a temp-table from another data member definition (such as a ProDataSet) defined in the same class or class hierarchy, the access mode of the temp-table cannot be more restrictive than the access mode of the referencing data member.

A temp-table defined with the STATIC option is a static data member of the class type for which it is defined, and it is scoped to the ABL session where it is referenced. ABL creates one copy of the specified class static temp-table at the first reference to the class type, and creates only one such copy for any number of instances of the class that you create. You cannot specify STATIC if you specify the REFERENCE-ONLY option. You can directly reference an accessible static temp-table data member from any other static or instance class member defined in the same class or class hierarchy.

Without the STATIC option, ABL creates an instance temp-table data member that is scoped to a single instance of the class where it is defined. ABL creates one copy of the specified instance temp-table for each such class instance that you create. You cannot directly reference an instance temp-table data member from a STATIC class member definition defined within the same class or class hierarchy.

For more information on accessing temp-tables of different access modes and scopes, see the reference entry for Class-based data member access.

**Note:** Members of a class are grouped into six namespaces, including buffers/temp-tables, methods, variables/properties/events, ProDataSets, queries, and data-sources. Buffers and temp-tables defined as members of a class share the same namespace. There can be only one class member in this namespace with a given name.

For more information on where and how to define data members in a class, see the CLASS statement reference entry.

\[
\text{TEMP-TABLE } temp-table-name
\]

Defines and identifies a temp-table object in an interface, or for access only within the current external procedure or as a data member of the current class.
DEFINE TEMP-TABLE statement

NO-UNDO

Specifies that when a transaction is undone, changes to the temp-table records need not be undone. If you do not specify this option, all records in the temp-table are restored to their prior condition when a transaction is undone. The NO-UNDO option can significantly increase the performance for temp-table updates; use it whenever possible.

NAMESPACE-URI namespace

An optional CHARACTER constant that specifies the URI for the namespace of the temp-table.

NAMESPACE-PREFIX prefix

An optional CHARACTER constant that specifies the namespace prefix associated with the NAMESPACE-URI.

XML-NODE-NAME node-name

An optional CHARACTER constant that specifies the name of the XML element representing the temp-table in an XML Document. The default is temp-table-name. Use this option when the serialized name either contains invalid characters for an ABL name or the serialized name is an ABL keyword.

Note: If you set SERIALIZE-NAME but do not set XML-NODE-NAME, the AVM sets XML-NODE-NAME equal to SERIALIZE-NAME.

SERIALIZE-NAME serialize-name

An optional CHARACTER constant that specifies the name of the temp-table as it should appear when serialized, for example into JSON or XML. The default is temp-table-name. Use this option when the serialized name either contains invalid characters for an ABL name or the serialized name is an ABL keyword.

REFERENCE-ONLY

Specifies that the procedure defining this temp-table object is using the object definition only as a reference to a temp-table object that is defined and instantiated in another procedure or class, and specified as a parameter in the invocation of a RUN statement, a method in a class, or a user-defined function, using either the BY-REFERENCE or BIND option. The AVM does not instantiate the reference-only object. You cannot specify REFERENCE-ONLY if you specify the STATIC option.

Passing a reference-only temp-table object parameter to a local routine using either the BY-REFERENCE or BIND option allows the calling routine and the called routine to access the same object instance (instead of deep-copying the parameter).

Note: If you pass the parameter to a remote procedure, the AVM deep-copies the parameter on OUTPUT and the reference-only parameter is bound to that copy.

When you pass a temp-table parameter to a local routine using the BY-REFERENCE option, both the calling and called routines access the calling routine’s object instance (and ignore the called routine’s object instance). Since the called routine’s object instance is ignored, you should define the object as a reference-only object. When you define a
DEFINE TEMP-TABLE statement

reference-only temp-table object in the called routine and receive it from the calling routine using the BY-REFERENCE option, the AVM binds the definition of the object in the called routine to the object instance in the calling routine for the duration of the called routine. You cannot define a reference-only temp-table object in the calling routine and pass it to the called routine using the BY-REFERENCE option.

When you pass a temp-table parameter to a local routine using the BIND option, you can define a reference-only temp-table object in either the calling routine or the called routine as follows:

- When you define a reference-only temp-table object in the calling routine and pass it to the called routine using the BIND option, the AVM binds the calling routine to the object instance in the called routine. The reference-only object definition remains bound to the object instance until the routine containing the reference-only object definition is deleted or terminates. The parameter must be an OUTPUT parameter.

  Note: If you also define the temp-table object instance in the called routine as a reference-only object, you must bind the object in the called routine before returning to the calling routine.

- When you define a reference-only temp-table object in the called routine and receive it from the calling routine using the BIND option, the AVM binds the called routine to the object instance in the calling routine. The reference-only object definition remains bound to the object instance until the routine containing the reference-only object definition is deleted or terminates. The parameter must be an INPUT or INPUT-OUTPUT parameter.

In either case, you must specify the BIND option for the parameter in both the invocation of a RUN statement, a method in a class, or a user-defined function, and in the DEFINE PARAMETER statement.

Caution: Do not delete the object or routine to which a reference-only temp-table object is bound, or you might be left with references to an object that no longer exists.

A reference-only temp-table object can be a member of a reference-only ProDataSet object or a standard ProDataSet object. However, if you define a reference-only temp-table in a standard ProDataSet object, you cannot use the ProDataSet object until you bind the reference-only temp-table.

LIKE table-name [ USE-INDEX index-name [ AS PRIMARY ] ] . . .

Specifies the name of a table whose characteristics the temp-table inherits. All field definitions of table-name are added to the temp-table. table-name can represent a database table or another temp-table.

Note: The source (temp-table or database table) for table-name can have any access mode or scope as long as its definition is accessible to the current temp-table definition.

If you reference a database field, the database containing that field must be connected at compile time. If the database field has a validation expression defined in the dictionary that
contains a database reference, and the VALIDATE option is specified, the database must also be connected at run-time.

HELP options are inherited from the table-name. Validate options are inherited only if the VALIDATE keyword is used.

Some index definitions from the specified table might also be added to the temp-table:

- If you use the USE-INDEX option, only the definitions of indexes you specify with that option are copied to the temp-table. If one of these indexes is the primary index of the LIKE table, it becomes the default primary index of the temp-table. You can, however, use the AS PRIMARY option to override this default primary index.

For example, to make the index country-post the primary index (thereby, overriding the default primary index CustNum in the table Customer), you specify it as follows:

```
DEFINE TEMP-TABLE mycust LIKE Customer
   USE-INDEX CustNum USE-INDEX country-post AS PRIMARY.
```

- If you do not specify the USE-INDEX option and do not use the INDEX option of the DEFINE TEMP-TABLE statement, then all index definitions are copied from the specified table to the temp-table. In this case, the primary index of the specified table becomes the primary index of the temp-table.

- If you do not specify the USE-INDEX option but do use the INDEX option of the DEFINE TEMP-TABLE statement, then no indexes are copied from the specified table.

- The AVM does not copy inactive indexes to the temp-table.

- If the source database table contains inactive indexes, then you must specify one or both of the USE-INDEX and INDEX options. If you do not, a compile time error is generated.

LIKE-SEQUENTIAL table-name [ USE-INDEX index-name [ AS PRIMARY ] ] . . .

Specifies the name of a table whose characteristics the temp-table inherits. All field definitions of table-name are added to the temp-table. table-name can represent a database table or another temp-table.

LIKE-SEQUENTIAL is similar to LIKE in all ways except one. Unlike LIKE, which creates temp-table fields in _field__field-rpos order (POSITION order in the .df schema definition file) of the source table’s fields, LIKE-SEQUENTIAL creates fields in _field__order sequence.

You can guarantee agreement of temp-table field order between any client and any AppServer using LIKE-SEQUENTIAL, as long as the _field__order values are the same. LIKE-SEQUENTIAL uses the field order as defined in the Data Dictionary when the source is a database table.

**Note:** The original behavior of LIKE was used to support RAW-TRANSFER with temp-tables. If you are using RAW-TRANSFER between a database table and a
DEFINE TEMP-TABLE statement

When you define a temp-table, you can optionally specify the LIKE option to define additional fields for the temp-table. If you try to modify the records in this before-image table, the AVM generates a run-time error. You cannot define a field in a database table as a class.

Note: When a temp-table contains one or more fields defined with the Progress.Lang.Object class, you cannot pass the temp-table to an AppServer.

LIKE field

Specifies a database field or a variable whose characteristics the temp-table field inherits. If you name a variable with this option, that variable must have been defined earlier in the procedure. The temp-table field inherits the data type, extents, format, initial value, label, and column label.
If the database field is a \texttt{COLUMN-CODEPAGE} CLOB, the temp-table field is in the database field’s code page. If the database field is a \texttt{DBCODEPAGE} CLOB, the temp-table field’s code page is \texttt{-cpinternal}.

You can override selected characteristics of the field or variable with the \texttt{field-options} parameter.

If you reference a database field in the LIKE option, the database containing that field must be connected at both compile time and run time. Therefore, use the LIKE option with caution.

\textit{field-options}

Specifies options for the temp-table field. Any options you specify override any options inherited through the LIKE option. This is the syntax for \texttt{field-options}:

\begin{verbatim}
{
    [ BGCOLOR expression ]
    [ COLUMN-LABEL label ]
    [ DCOLOR expression ]
    [ DECIMALS n ]
    [ EXTENT n ]
    [ FONT expression ]
    [ FGCOLOR expression ]
    [ FORMAT string ]
    [ HELP help-text ]
    [ INITIAL
        { [ constant ]
        [ [ constant [ , constant ] ... ] ]
    ]
    [ LABEL label [ , label ] ... ]
    [ MOUSE-POINTER expression ]
    [ [ NOT ] CASE-SENSITIVE ]
    [ PFCOLOR expression ]
    [ SERIALIZE-HIDDEN ]
    [ SERIALIZE-NAME serialize-name ]
    [ TTCODEPAGE | COLUMN-CODEPAGE codepage ]
    [ XML-DATA-TYPE string ]
    [ XML-NODE-TYPE string ]
    [ XML-NODE-NAME node-name ]
    [ view-as-phrase ]
}
\end{verbatim}

\texttt{HELP help-text}

A quoted CHARACTER string that represents the help text.

\texttt{SERIALIZE-HIDDEN}

Indicates that this field is not written when the temp-table is serialized, for example into JSON or XML.
Note: If you also specify XML-NODE-TYPE, the WRITE-XML( ) method uses the value of XML-NODE-TYPE and ignores this option.

SERIALIZE-NAME serialize-name

An optional CHARACTER constant that specifies the name of the temp-table as it should appear when serialized, for example into JSON or XML. The default is temp-table field-name. Use this option when the serialized name either contains invalid characters for an ABL name or the serialized name is an ABL keyword.

Note: If you also specify XML-NODE-NAME, the READ-XML( ) and WRITE-XML( ) methods use the value of XML-NODE-NAME and ignore this option.

TTCODEPAGE | COLUMN-CODEPAGE codepage

Specifies the code page for a CLOB field in the temp-table. If you specify TTCODEPAGE, the code page is -cpinternal. If you specify COLUMN-CODEPAGE, codepage must be a valid code page name available in the DLC/convmap.cp file. You cannot specify the "undefined" code page for a CLOB. The code page you specify overrides any code page inherited through the LIKE option.

If you do not specify a code page for a CLOB field in the temp-table, the default code page is -cpinternal.

XML-DATA-TYPE string

An optional CHARACTER constant that specifies the XML Schema data type for the field in the temp-table. The XML Schema data type must be compatible with the ABL data type for the field.

For more information about the ABL XML data type mapping rules, see OpenEdge Development: Working with XML.

XML-NODE-TYPE string

An optional CHARACTER constant that specifies the XML node type of the temp-table field, which lets you specify how the field is represented in XML. Valid XML node types are: "ATTRIBUTE", "ELEMENT", "HIDDEN", and "TEXT". The default value is "ELEMENT".

Table 33 lists the valid XML node types.

Table 33: XML node types

<table>
<thead>
<tr>
<th>When the XML node type is . . .</th>
<th>The buffer field is . . .</th>
</tr>
</thead>
<tbody>
<tr>
<td>ATTRIBUTE</td>
<td>Represented as an attribute of the temp-table element in both the XML Schema and data.</td>
</tr>
<tr>
<td>ELEMENT</td>
<td>Represented as a child element of the temp-table element in both the XML schema and data.</td>
</tr>
</tbody>
</table>
The XML node type of a temp-table field that represents an array must be either "ELEMENT" or "HIDDEN".

**Note:** If you specify SERIALIZE-HIDDEN but do not set XML-NODE-TYPE, the AVM sets XML-NODE-TYPE to "HIDDEN".

**XML-NODE-NAME**  
\textit{node-name}

An optional CHARACTER constant that specifies the name of the XML element or XML attribute representing the temp-table field in an XML Document. The default is the temp-table \textit{field-name}.

**Note:** If you set SERIALIZE-NAME but do not set XML-NODE-NAME, the AVM sets XML-NODE-NAME equal to SERIALIZE-NAME.

**Note:** You cannot specify an indeterminate array field in a temp-table using the EXTENT field option.

For more information and a description of all other field options, see the DEFINE VARIABLE statement.

**INDEX**  
\textit{index-name} [ [ AS | IS ] [ UNIQUE ] [ PRIMARY ] [ WORD-INDEX ] ]

Defines an index on the temp-table. To define a unique index, specify the UNIQUE option. To define the primary index, specify the PRIMARY option. To define a word-index, specify the WORD-INDEX option.

If you define more that one index on the temp-table, you can specify PRIMARY for none or one of the indexes. If you specify PRIMARY for none of the indexes, the AVM makes the first index you specify the primary index.

If you define no indexes on the temp-table, and the temp-table does not inherit the indexes of another table through the LIKE option of the DEFINE TEMP-TABLE statement, the AVM creates a default index, makes it the primary index, and sorts the records in entry order.
**index-field [ ASCENDING | DESCENDING ]**

Specifies a temp-table field to use as a component of the index. You can use the ASCENDING or DESCENDING option to specify that the component has ascending or descending order.

If you do not specify a sort orientation (ASCENDING or DESCENDING), the index component gets the sort orientation of the previous index component, or, if there is no previous index component, ASCENDING. This rule applies only to index components of temp-tables.

**Note:** You cannot use a BLOB or CLOB field as a component of an index.

For example, the following two temp-table definitions are equivalent:

```
DEFINE TEMP-TABLE foo NO-UNDO
  FIELD a AS CHARACTER
  FIELD b AS CHARACTER
  FIELD c AS CHARACTER
  INDEX x a DESC b DESC c DESC.
```

The following two temp-table definitions are also equivalent:

```
DEFINE TEMP-TABLE foo NO-UNDO
  FIELD a AS CHARACTER
  FIELD b AS CHARACTER
  FIELD c AS CHARACTER
  INDEX x a DESC b c.
```

**Examples**

The following procedure creates a temp-table (temp-item) that stores the total inventory value (Item.Price * Item.OnHand) for each catalog page (Item.CatPage) in the sports2000 database. It builds temp-item with two indexes—one that sorts the table in ascending order by catalog page and a second that sorts the table in descending order by inventory value.
DEFINE TEMP-TABLE statement

After building temp-item, the procedure displays a dialog box that prompts for report parameters. These parameters include the cutoff value of catalog page inventory to report, and whether to display the report by catalog page (ascending) or inventory value (descending). After displaying the report, the procedure displays another dialog box to repeat the process. The process is repeated until you press the CANCEL button. This procedure shows how you can use a temp-table to store a calculated result from the database, and efficiently report the same result according to different sorting and selection criteria:

**r-tmptb1.p**

```plaintext
DEFINE TEMP-TABLE temp-item
    FIELD cat-page LIKE Item.CatPage
    FIELD inventory LIKE Item.Price LABEL "Inventory Value"
    INDEX cat-page IS PRIMARY cat-page ASCENDING
    INDEX inventory-value inventory DESCENDING.
DEFINE VARIABLE cutoff NO-UNDO LIKE item.price.
DEFINE VARIABLE inv-value NO-UNDO LIKE item.price.
DEFINE VARIABLE report-type AS INTEGER NO-UNDO INITIAL 1.
DEFINE BUTTON ok-butt LABEL "OK" AUTO-GO.
DEFINE BUTTON cancel-butt LABEL "CANCEL" AUTO-ENDKEY.
FORM
cutoff LABEL "Inventory Lower Cutoff for each Catalog Page"
    AT ROW 1.25 COLUMN 2
REPORT-type LABEL "Report Sorted ..." AT ROW 2.25 COLUMN 2

For examples of instance and static temp-table data member definitions, see the descriptions of `r-CustObj.cls`, `r-CustObjStatic.cls`, and `r-CustObjAbstract.cls` in the CLASS statement reference entry.
DEFINE TEMP-TABLE statement

Notes

• If you define a temp-table LIKE a database table, the temp-table does not inherit the database table’s database triggers.

• You cannot define a temp-table field of type MEMPTR or LONGCHAR.

• You cannot define shared objects, work tables, or temp-tables within an internal procedure, a method in a class, or a user-defined function.

• A temp-table can be compile-time defined (often referred to as a static temp-table object), where the temp-table is defined and created at compile time using this statement, or it can be run-time defined (often referred to as a dynamic temp-table object), where the temp-table is defined and created at run time using the CREATE TEMP-TABLE statement and temp-table object handle operations. A compile-time defined temp-table can also be defined as a static data member of a class. In this case, it is a static temp-table object that is also a class static data member.

• ABL disregards the following options when used in conjunction with a temp-table:
  – The VALIDATE option on a DELETE statement.
  – The SHARE-LOCK, EXCLUSIVE-LOCK, and NO-LOCK options used with the FIND or FOR statements.
  – The NO-WAIT option on the FIND statement.

• Data handling statements that cause the AVM to automatically start a transaction for a regular table will not cause the AVM to automatically start a transaction for a temp-table. If you want to start a transaction for operations involving a temp-table, you must explicitly start a transaction by using the TRANSACTION keyword.

• Use the CASE-SENSITIVE option only when it is important to distinguish between uppercase and lowercase values entered for a character field. For example, use CASE SENSITIVE to define a field for a part number that contains mixed upper-case and lowercase characters.

• You cannot define a SHARED or NEW SHARED temp-table in a class definition (.cls) file. If you do, ABL generates a compilation error.

• A SHARED temp-table remains in scope for an instance of a persistent procedure until the instance is deleted. This is true even if the original procedure that defined the temp-table as NEW SHARED goes out of scope while the procedure instance remains persistent.

  If a trigger or internal procedure of a persistent procedure executes an external subprocedure that defines a SHARED temp-table, ABL includes the persistent procedure in the resolution of the corresponding NEW SHARED temp-table as though the procedure were on the procedure call stack.

• You can specify a join between a temp-table or work table and any appropriate table using the OF keyword. The two tables must contain a commonly named field that participates in a unique index for at least one of the tables. For more information on table joins see the Record phrase reference entry.

• If you define a temp-table with the same name as a database table and then you define a buffer for that name, the buffer will be associated with the database table, not with the temp-table.
• The point at which the AVM stores temp-table overflow from memory to disk is based on the setting of the Number of Buffers for Temp-tables (-Bt) startup parameter, which specifies the number of buffers in the temp-table database pool. For more information, see OpenEdge Deployment: Startup Command and Parameter Reference.

• See OpenEdge Getting Started: ABL Essentials for information on temp-tables and work tables.

DEFINE VARIABLE statement

Defines a variable for use in one or more procedures, a variable data member of a class for use in a single class or class hierarchy, or by other classes and procedures, or a variable data element for use within a single class-based method.

Syntax

```
DEFINE { [ [ NEW [ GLOBAL ] ] | [ PRIVATE | PROTECTED | PUBLIC ] | [ SHARED ] ] | [ STATIC ] }
VARIABLE variable-name
{ { AS [ HANDLE TO ] primitive-type-name
  | AS [ CLASS ] { object-type-name }
  | LIKE field }
  [ EXTENT [ constant ] ] }
[ BGCOLOR expression ]
[ COLUMN-LABEL label ]
[ CONTEXT-HELP-ID expression ]
[ DCOLOR expression ]
[ DECIMALS n ]
[ DROP-TARGET ]
[ FONT expression ]
[ FGCOLOR expression ]
[ FORMAT string ]
[ INITIAL
  { constant | { [constant | , constant ] ... } } ]
[ LABEL string [ , string ] ... ]
[ MOUSE-POINTER expression ]
[ NO-UNDO ]
[ [ NOT ] CASE-SENSITIVE ]
[ PFCOLOR expression ]
{ [ view-as-phrase ] }
{ [ trigger-phrase ] }
```
**NEW SHARED VARIABLE** *variable-name*

Defines and identifies a variable to be shared by a procedure called directly or indirectly by the current procedure. The called procedure must name the same variable in a DEFINE SHARED VARIABLE statement.

**NEW GLOBAL SHARED VARIABLE** *variable-name*

Defines and identifies a variable that can be used by any procedure that names that variable using the DEFINE SHARED VARIABLE statement. The value of a global shared variable remains available throughout an ABL session.

**SHARED VARIABLE** *variable-name*

Defines and identifies a variable that was created by another procedure that used the DEFINE NEW SHARED VARIABLE or DEFINE NEW GLOBAL SHARED VARIABLE statement.

**[PRIVATE | PROTECTED | PUBLIC ] [ STATIC ] VARIABLE** *variable-name*

Defines and identifies a variable as a data member of a class, and optionally specifies an access mode (PRIVATE, PROTECTED, or PUBLIC) and scope (instance or STATIC) for that data member. You cannot specify these options when defining a variable as a data element of a method (including constructors, destructors, and property accessors) or procedure.

**Note:** The specified options are applicable only when defining a data member for a class in a class definition (.cls) file. Note also that you cannot shadow (override) the definition of a given variable data member in a class hierarchy.

PRIVATE variable data members can be accessed only by the defining class. PROTECTED variable data members can be accessed by the defining class and any of its derived classes. PUBLIC variable data members can be accessed by:

- The defining class
- Any of its derived classes
- Any class or procedure that has access to a class instance that defines or inherits the variable data member

Any piece of code can access a PUBLIC static variable data member. The default access mode is PRIVATE.

A variable defined with the STATIC option is a static data member of the class type for which it is defined and is scoped to the ABL session where it is referenced. ABL creates one copy of the specified class static variable on first reference to the class type, and ABL creates only one such copy for any number of instances of the class that you create. You can reference an accessible static variable data member in any piece of code.

Without the STATIC option, ABL creates an instance variable data member that is scoped to a single instance of the class where it is defined. ABL creates one copy of the specified instance variable for each such class instance that you create. You can reference any public instance variable in any procedure, or in any instance or static method defined inside or outside of the class where the instance variable is defined. Any static method can reference
the public instance variable only using an object reference to a class instance that defines
the variable as a data member. If the referencing static method is defined in the same class
as the public instance variable, the class must instantiate itself in order to have access to
an instance reference.

You can reference a private or protected instance variable only in instance methods that
are defined inside the same class or class hierarchy.

**Note:** You cannot use a class instance that is not equal to the THIS-OBJECT system
reference to reference a private or protected instance variable that is defined in the
same class, because PRIVATE and PROTECTED access modes are instance based
in ABL. Thus, private and protected instance members are accessible only to other
members of the same class instance, where as public instance members can be
accessed from other instances of the same class, including the session “static
instance” of the class.

For more information on the mechanism for accessing variable data members of different
access modes and scopes, see the reference entry for Class-based data member access.

**Note:** Members of a class are grouped into six namespaces, including
buffers/temp-tables, methods, variables/properties/events, ProDataSets, queries,
and data-sources. Variables, properties, and events defined as members of a class
share the same namespace. There can be only one class member in this namespace
with a given name (not counting abstract member overrides).

If `variable-name` is an ABL reserved keyword, you must include an access mode of
PUBLIC, PROTECTED, or PRIVATE in its definition. You must also use the
THIS-OBJECT system reference or Type-name syntax to access the variable data
member. For more information on referencing variable data members, see the reference
entry for Class-based data member access.

**Note:** If the data member is defined in a class that is derived from a .NET class, other
restrictions on `variable-name` apply. For more information, see the CLASS
statement reference entry.

For more information on where and how to define data members in a class, see the CLASS
statement reference entry.

**VARIABLE** `variable-name`

Defines and identifies a variable whose value you can access only within the current
procedure, method of a class (including constructors, destructors, and property accessors),
or as a private data member of a class.

**AS** `primitive-type-name`

Specifies a built-in primitive type for the variable you are defining. The built-in data type
(`primitive-type-name`) can be one of the following:
DEFINE VARIABLE statement

For more information on these primitive types, see the Data types reference entry.

AS [ CLASS ] \{ object-type-name \}

Defines the variable as an object reference with the data type of a class or interface. The default value of the variable is the Unknown value (?). You cannot assign an initial value using the INITIAL option.

object-type-name

Specifies the type name of an ABL or .NET class or interface. Specify an object type name using the syntax described in the Type-name syntax reference entry. With an appropriate USING statement, you can also specify a class or interface name alone, without the qualifying package or namespace.

You cannot directly specify the type name of a .NET mapped object type (such as System.Int32). To define a variable that matches a .NET mapped type, you must define it as the corresponding ABL primitive type (primitive-type-name).

CLASS

If the specified class or interface type name conflicts with an abbreviation for a built-in primitive type name, such as INT for INTEGER, you must specify the CLASS keyword.

For more information on object references, see the Class-based object reference reference entry.

LIKE field

Indicates the name of the variable, database field, temp-table field, or work table field whose characteristics you want to use for the variable you are defining. If you name a variable with this option, you must have defined that variable earlier in the procedure. You can override the format, label, initial value, decimals, and extent of the variable or database field by using the FORMAT, LABEL, COLUMN-LABEL, INITIAL, DECIMALS, EXTENT, and VIEW-AS options. If you do not use these options, the variable takes on the characteristics of the variable or database field you name.

If field has help and validate options defined, the variable you are defining does not inherit those characteristics.

If you reference a database field in a LIKE option in a DEFINE VARIABLE statement, DEFINE TEMP-TABLE statement, DEFINE WORK-TABLE statement, or format phrase, the database containing the referenced field must be connected at both compile time and run time. Therefore, use the LIKE option with caution.

EXTENT [ constant ]

Defines the variable as an array of data elements, where the element data type is specified by the AS primitive-type-name option, the LIKE field option, or the AS

| CHARACTER | COM-HANDLE | DATE | DATETIME | DATETIME-TZ | DECIMAL |
| HANDLE | INT64 | INTEGER | LOGICAL | LONGCHAR | MEMPTR | RAW | RECID |
| ROWID |
object-type-name option. This option can specify an array variable as either determinate (has a defined number of elements) or indeterminate (has an undefined number of elements). To define a determinate array variable, specify the EXTENT option with the constant argument. This optional argument is an integer value that represents the number of data elements in the array variable. To define an indeterminate array variable, specify the EXTENT option without the constant argument.

The EXTENT is part of the variable data type. For more information, see the Type-name syntax reference entry.

An indeterminate array variable can be in one of two states: fixed or unfixed, meaning it either has a fixed dimension or it does not. An indeterminate array variable has an unfixed dimension when first defined. You can fix the dimension of an indeterminate array variable by:

- Initializing the array values when you define the variable, using the INITIAL option
- Setting the number of elements in the array variable using the EXTENT statement
- Assigning a determinate array to the indeterminate array, fixing it to the dimension of the determinate array
- Passing array parameters to a procedure, user-defined function, or class-based method, so that the indeterminate array variable is the target for the passing of a determinate array, fixing the indeterminate array to the dimension of the determinate array

Once fixed, ABL treats a fixed indeterminate array as a determinate array.

If you want to define a variable that is like an array variable or field, using the LIKE option, but you do not want the variable to be an array, you can use EXTENT 0 to indicate a non-array field.

If you are using the AS option and you do not use the EXTENT option (or you specify constant as 0), the variable is not an array variable. If you are using the LIKE field option and you do not use the EXTENT option, the variable uses the extent defined for the database field you name (if any).

BGCOLOR expression

Specifies a background color for the variable in graphical interfaces. This option is ignored in character interfaces.

[ NOT ] CASE-SENSITIVE

CASE-SENSITIVE indicates that the value stored for a character variable is case sensitive, and that all comparisons operations involving the variable are case sensitive. If you do not use this option, ABL comparisons are usually case insensitive. If you define a variable LIKE another field of variable, the new variable inherits case sensitivity. Use [NOT] CASE-SENSITIVE to override this default.

COLUMN-LABEL label

Names the label you want to display above the variable data in a frame that uses column labels. If you want the label to use more than one line (a stacked label), use an exclamation point (!) in the label to indicate where to break the line. For example:
If you want to use the exclamation point (!) as one of the characters in a column label, use two exclamation points (!!).

The AVM does not display column labels if you use the SIDE-LABELS or NO-LABELS options with the Frame phrase.

If you define a variable to be LIKE a field, and that field has a column label in the Data Dictionary, the variable inherits that column label.

**CONTEXT-HELP-ID expression**

An integer value that specifies the identifier of the help topic for this variable in a help file specified at the session, window or dialog box level using the CONTEXT-HELP-FILE attribute.

**DCOLOR expression**

Specifies the display color for the variable in character interfaces. This option is ignored in graphical interfaces.

**DECIMALS n**

Specifies the number of decimal places to store for a DECIMAL variable, where n is an integer constant. When you define a variable AS DECIMAL, ABL automatically stores up to 10 decimal places for the value of that variable. Use the DECIMALS option to store a smaller number of decimal places. The DECIMALS option has nothing to do with the display format of the variable, just the storage format.

If you use the LIKE option to name a field whose definition you want to use to define a variable, ABL uses the number of decimals in the field definition to determine how many decimal places to store for the variable.

**Note:** The XML-WRITE() method on a temp-table, temp-table buffer, or ProDataSet object also uses the DECIMALS attribute to determine the number of decimal places to export to the XML Document.

**DROP-TARGET**

Indicates whether you want to be able to drop a file onto the object.

The following example shows setting the DROP-TARGET option for a variable:
DEFINE VARIABLE statement

DEFINE VARIABLE fill-in-1 AS CHARACTER DROP-TARGET.

FGCOLOR expression

Specifies a foreground color for the variable in graphical interfaces. This option is ignored in character interfaces.

FONT expression

Specifies a font for the variable.

FORMAT string

The data format of the variable you define. If you use the AS primitive-type-name option and you do not use FORMAT string, the variable uses the default format for its data type. Table 34 lists the default data formats for the data types.

<table>
<thead>
<tr>
<th>Data type</th>
<th>Default display format</th>
</tr>

</tr>
<tr>
<td>ROWID¹</td>
<td>See the footnote at the end of this table.</td>
</tr>
</tbody>
</table>
DEFINE VARIABLE statement

1. You cannot display a BLOB, CLOB, MEMPTR, RAW, or ROWID value directly. However, you can convert
   a MEMPTR, RAW, or ROWID value to a character string representation using the STRING function and
display the result. You can also convert a BLOB to a MEMPTR, and then use the STRING function. A
MEMPTR or RAW value converts to decimal integer string. A ROWID value converts to a hexadecimal
string, "0xhexdigits," where hexdigits is any number of characters "0" through "9" and "A" through "F".
You can display a CLOB field by converting it to a LONGCHAR, and displaying the LONGCHAR using the
VIEW-AS EDITOR LARGE phrase only.

2. If you display a class instance using the MESSAGE statement, ABL automatically invokes the ToString( )
method (provided by the Progress.Lang.Object class) on the object reference. To display a class instance
in a frame (for example, using the DISPLAY statement), you must first explicitly convert the object reference
to a displayable type using the INT64 function, the INTEGER function, the STRING function, or the
ToString( ) method.

See OpenEdge Getting Started: ABL Essentials for more information on data formatting.

If you use the LIKE field option and you do not use the FORMAT string option, the
variable uses the format defined for the database field you name. You must enclose the
string in quotes.

}\{ constant | [ constant , constant ] . . . \}

The initial value of the variable you want to define. If you use the AS
primitive-type-name option and you do not use the INITIAL constant option, the
default is the initial value for the data type of the variable or array element.

When you define an array variable, you can supply initial values for each element in the
array. For example:

```
DEFINE VARIABLE array-var AS CHARACTER NO-UNDO EXTENT 3
   INITIAL ["Add","Delete","Update").
```

If you do not supply enough values to fill up the elements of the array, the AVM puts the
last value you named into the remaining elements of the array. If you supply too many
values, the AVM raises an error.

If you define a variable as an indeterminate array, and you supply initial values for
elements in the array, the AVM fixes the number of elements in the array and treats the
fixed indeterminate array as a determinate array. For example, the arrays defined by the
following statements are equivalent:

```
DEFINE VARIABLE x AS INTEGER NO-UNDO EXTENT INITIAL [1,2,3].
DEFINE VARIABLE x1 AS INTEGER NO-UNDO EXTENT 3 INITIAL [1,2,3].
```

You can also use the EXTENT statement to fix the number of elements in an unfixed
indeterminate array variable. For more information, see the EXTENT statement reference
entry.

Table 35 lists the default initial values for the various variable data types.
DEFINE VARIABLE statement

Table 35: Default variable initial values

</tr>
<tr>
<td>ROWID(^2)</td>
<td>Unknown value (?)</td>
</tr>
</tbody>
</table>

1. If you display a class instance using the MESSAGE statement, ABL automatically invokes the ToString( ) method (provided by the Progress.Lang.Object class) on the object reference. To display a class instance in a frame (for example, using the DISPLAY statement), you must first explicitly convert the object reference to a displayable type using the INT64 function, the INTEGER function, the STRING function, or the ToString( ) method.

2. You cannot use the INITIAL option to specify an initial value for this data type as part of the variable definition.

If you are using the LIKE field option and you do not use the INITIAL constant option, the variable uses the initial value of the field or variable. In the DEFINE SHARED VARIABLE statement, the INITIAL option has no effect. However, the DEFINE NEW SHARED VARIABLE, the DEFINE NEW SHARED TEMP-TABLE, and the DEFINE NEW WORK-TABLE statements work with the INITIAL option.

LABEL string [ , string ] ... 

The label you want to use when the variable is displayed. If you use the AS primitive-type-name option and you do not use the LABEL string option, the default label is the variable name. If you use the LIKE field option and you do not use the LABEL string option, the variable uses the label of the field or variable you name. You must enclose the string in quotes.
You can specify a label for each element in a determinate array variable. You cannot specify a label for elements in an indeterminate array variable.

In MS-Windows, you can designate a character within each label as a navigation mnemonic. Precede the character with an ampersand (&). When the variable is displayed with side labels, the mnemonic is underlined. The user can move focus to the variable by pressing ALT and the underlined letter. Navigation mnemonics operate only when you use side labels. If you specify more than one widget with the same mnemonic, the AVM transfers focus to each of these in tab order when you make a selection.

Ending a label with an ampersand might produce unwanted behavior. To include a literal ampersand within a label, specify a double ampersand (&&).

MOUSE-POINTER expression

Specifies the default mouse pointer for the variable.

NO-UNDO

When the value of a variable is changed during a transaction and the transaction is undone, the AVM restores the value of the variable to its prior value. If you do not want, or if you do not need, the value of a variable to be undone even when it has been changed during a transaction, use the NO-UNDO option with the DEFINE VARIABLE statement. NO-UNDO variables are more efficient; use this option whenever possible.

Specifying NO-UNDO for a variable is especially useful if you want to indicate an error condition as the value of the variable, perform an UNDO, and later take some action based on that error condition. If one variable is defined LIKE another that is NO-UNDO, the second variable will be NO-UNDO only if you specify NO-UNDO in the definition of the second variable.

PFCOLOR expression

Specifies the prompt-for color for the variable in character interfaces. This option is ignored in graphical interfaces.

view-as-phrase

Specifies the default data representation widget for this variable. Following is the syntax for the view-as-phrase:
DEFINE VARIABLE statement

```
VIEW-AS
{ combo-box-phrase
  | editor-phrase
  | FILL-IN
    [ NATIVE ]
    [ size-phrase ]
    [ TOOLTIP tooltip ]
  | radio-set-phrase
  | selection-list-phrase
  | slider-phrase
  | TEXT
    [ size-phrase ]
    [ TOOLTIP tooltip ]
  | TOGGLE-BOX
    [ size-phrase ]
    [ TOOLTIP tooltip ]
}
```

For more information on `view-as-phrase`, see the VIEW-AS phrase reference entry.

`trigger-phrase`

Defines triggers for the data representation widget specified in the `view-as-phrase`. Following is the syntax for the `trigger-phrase`:

```
TRIGGERS:
{ ON event-list [ ANYWHERE ]
  { trigger-block
    | PERSISTENT RUN proc-name
      [ IN handle ]
      [ ( input-parameters ) ]
  }
}
END [ TRIGGERS ]
```

For more information on triggers, see the Trigger phrase reference entry.

**Examples**

The `r-dfvar.p` procedure defines two variables, `del` and `nrecs` to be shared with procedure `r-dfvar2.p`. The `del` variable passes information to `r-dfvar2.p`, while `nrecs` passes information back to `r-dfvar.p` from `r-dfvar2.p`. 

- `r-dfvar.p`: Procedure defines two variables, `del` and `nrecs.` The `del` variable passes information to `r-dfvar2.p`, while `nrecs` passes information back to `r-dfvar.p` from `r-dfvar2.p`.
The following example is a startup procedure. It defines a new global variable with the initial value TRUE and uses that variable to determine whether to run an initialization procedure, `r-init.p`, that displays sign-on messages. Then the global variable `first-time` is set to FALSE. If you restart this procedure during the same session (pressed STOP), `r-init.p` does not run again.

The procedure also defines the variable selection for entering menu choices within this procedure:
The following procedure finds the day of the week of a date the user enters. The procedure defines an array with seven elements and uses the INITIAL option to define the initial value of each element in the array.

```
r-dfvar3.p
DEFINE NEW GLOBAL SHARED VARIABLE first-time AS LOGICAL NO-UNDO INITIAL TRUE.
DEFINE VARIABLE selection AS INTEGER NO-UNDO FORMAT "9" LABEL "Selection".
IF first-time THEN DO:
  RUN r-init.p.
  first-time = FALSE.
END.
FORM
  " MAIN MENU " SKIP(1)
  "1 - Accounts Payable " SKIP
  "2 - Accounts Receivable"
  WITH CENTERED ROW 5 FRAME menu.
REPEAT:
  VIEW FRAME menu.
  UPDATE selection AUTO-RETURN WITH FRAME sel CENTERED ROW 12 SIDE-LABELS.
  IF selection = 1 THEN DO:
    HIDE FRAME menu.
    HIDE FRAME sel.
    RUN apmenu.p.
  END.
  ELSE IF selection = 2 THEN DO:
    HIDE FRAME menu.
    HIDE FRAME sel.
    RUN armenu.p.
  END.
  ELSE DO:
    MESSAGE "Invalid selection. Try again".
    UNDO, RETRY.
  END.
END.
```

The following example defines a variable with a VIEW-AS phrase and a Trigger phrase:
DEFINE VARIABLE statement

For examples of instance and static variable data member definitions, see the descriptions of r-CustObj.cls, r-CustObjStatic.cls, and r-CustObjAbstract.cls in the CLASS statement reference entry.

Notes

- You can use the DEFINE VARIABLE statement anywhere. However, all references to the variable must appear after the DEFINE VARIABLE statement that defines it.

- You cannot define a variable as a BLOB or CLOB field. You can define a variable using their MEMPTR and LONGCHAR counterparts, respectively.

- A HANDLE variable defined as a static data member can reference the handle of any compile-time defined (static) or run-time defined (dynamic) handle-based object, such as a button, temp-table, or ProDataSet.

- Defining a LONGCHAR variable supports the same options as a CHARACTER variable, except for the FORMAT option and all VIEW-AS options except VIEW-AS EDITOR LARGE.

- You should use the CASE-SENSITIVE option only when it is important to distinguish between uppercase and lowercase values entered for a character variable. For example, use CASE-SENSITIVE to define a variable for a part number that contains mixed uppercase and lowercase characters.

- After you use the DEFINE NEW GLOBAL SHARED VARIABLE statement to create a global shared variable, use the DEFINE SHARED VARIABLE statements in other procedures to access that variable.

- You cannot define the same global variable twice in the same ABL session. If you try, and the definitions of the two variables do not match, the AVM raises an error. If the definitions of the two variables match, the AVM disregards the second variable you tried to define (if you are rerunning a startup procedure).

- Changes made to variables when there is no active transaction are not undone when a block is undone.
• When a procedure names and uses a shared variable:
  – The AVM searches through the calling chain of procedures looking for the most recent DEFINE NEW SHARED VARIABLE statement that created that shared variable.
  – If no DEFINE NEW SHARED VARIABLE statement is found, the AVM searches for a DEFINE NEW GLOBAL SHARED VARIABLE statement that created the shared variable.
  – If the procedure that names the shared variable is called from a trigger or internal procedure that is part of a persistent procedure context, the persistent context is also checked for the most recent DEFINE NEW SHARED VARIABLE or DEFINE NEW GLOBAL SHARED VARIABLE statement at the point in the calling chain where the trigger or internal procedure is executed.
  – If the AVM finds one of these statements, it does not search any further for other statements that might have defined the same variable as NEW or NEW GLOBAL.

• The AVM checks the definition of a SHARED variable against that of the corresponding NEW SHARED or NEW GLOBAL SHARED variable. The data types and array extents must match. If the FORMAT, LABEL and DECIMALS specifications are not the same, each procedure uses its individual specification. The DEFINE NEW SHARED statement determines if a shared variable is NO-UNDO.

• A SHARED variable remains in scope for an instance of a persistent procedure until the instance is deleted. This is true even if the original procedure that defined the variable as NEW SHARED goes out of scope while the procedure instance remains persistent.

If a trigger or internal procedure of a persistent procedure executes an external subprocedure that defines a SHARED variable, the AVM includes the persistent procedure in the resolution of the corresponding NEW SHARED variable as though the procedure were on the procedure call stack.

• If an application with several procedures defines a NEW SHARED variable with the same name in each procedure, the AVM creates a different instance of the NEW SHARED variable in each procedure. This behavior supports recursive procedures and bill-of-materials applications.

• You can neither define a SHARED or NEW SHARED variable, nor access such a variable defined in a procedure file, from within a class definition (.cls) file. If you do, ABL generates a compilation error. However, multiple procedure (.p) files can define and access an object reference variable for a class instance as a NEW SHARED or NEW GLOBAL SHARED variable. In this case, the object reference variables must be defined for the same class (not a subclass or a super class) in all procedures that use them.

• For SpeedScript, the following options are invalid: BGCOLOR, CONTEXT-HELP-ID, DCOLOR, FONT, FGCOLOR, MOUSE-POINTER, PFCOLOR, and view-as-phrase.

See also Class-based data member access, DEFINE BUFFER statement, RUN statement, Trigger phrase, Type-name syntax, USING statement, VIEW-AS phrase.
DEFINE WORK-TABLE statement

Defines a work table (a temp-table stored in memory) for use in one or more procedures, or within a single class.

This statement is supported only for backward compatibility. Use the DEFINE TEMP-TABLE statement, instead.

Syntax

```
DEFINE NEW SHARED { WORK-TABLE | WORKFILE } work-table-name
[ LIKE tablename [ VALIDATE ] ]
[ FIELD field-name { AS data-type | LIKE field } ]
[ field-options ] ... |
```

**NEW SHARED { WORK-TABLE | WORKFILE } work-table-name**

Defines and identifies a work table to be shared by a procedure called directly or indirectly by the current procedure. The called procedure must name the same work table in a DEFINE SHARED WORK-TABLE statement. The WORKFILE keyword is allowed only for backward compatibility; using WORK-TABLE or WORKFILE has the same effect.

**SHARED { WORK-TABLE | WORKFILE } work-table-name**

Defines and identifies a work table that was defined by another procedure that used the DEFINE NEW SHARED WORK-TABLE statement. The WORKFILE keyword is allowed only for backward compatibility; using WORK-TABLE or WORKFILE has the same effect.

**[ PRIVATE ] { WORK-TABLE | WORKFILE } work-table-name**

Defines and identifies a work-table as a class-scoped object. A class-scoped handle-based object is not a member of a class, but provides a resource that is privately available to the class definition similar to a non-shared data element in a procedure definition. The option to specify the PRIVATE access mode is provided for readability. You cannot specify PRIVATE when defining a work-table as a data element in a method or procedure. The WORKFILE keyword is allowed only for backward compatibility; using WORK-TABLE or WORKFILE has the same effect.

**Note:** This option is applicable only when defining a class-scoped work-table in a class definition (.cls) file.

**{ WORK-TABLE | WORKFILE } work-table-name**

Defines and identifies a work table whose records you can access only within the current procedure, class, or method of a class.

The WORKFILE keyword is allowed only for backward compatibility; using WORK-TABLE or WORKFILE has the same effect.
DEFINE WORK-TABLE statement

NO-UNDO

Specifies that the AVM should not restore the record to its prior condition when a work table record is changed during a transaction and the transaction is undone. If you do not want the work table record undone even if it has changed during a transaction, use the NO-UNDO option with the DEFINE WORK-TABLE statement. NO-UNDO work tables are more efficient; use them whenever possible.

LIKE table-name

Indicates the name of a table whose characteristics you want to use for the work table you are defining. All of the fields in this base table are also in the work table. If you reference a database table with the LIKE option, the database containing that table must be connected at compile time. It need not be connected at run time.

If more than one connected database contains a table named table-name, you must qualify the table name with the database name. See the Record phrase description for more information.

HELP options are inherited from the table-name. Validate options are inherited only if the VALIDATE keyword is used.

VALIDATE

The work table fields inherit, from the dictionary, validation expressions and validation messages from the database table, table-name.

FIELD field-name

Identifies the name of a field in the work table.

AS data-type

Indicates the data type of the field or variable you are defining. The data types are CHARACTER, COM-HANDLE, DATE, DATETIME, DATETIME-TZ, DECIMAL, HANDLE, INT64, INTEGER, LOGICAL, RAW, RECID, and ROWID.

For more information on these data types, see the Data types reference entry.

LIKE field

Indicates the name of the variable, database field, temp-table field, or work table field whose characteristics you want to use for the work table field you are defining. If you name a variable with this option, you must have defined that variable earlier in the procedure. The work table field inherits the data type, extents, format, initial value, label, and column label of the field. You can override specific values by using the FORMAT, LABEL, INITIAL, DECIMALS, and EXTENT options. If you do not use these options, the field or variable takes on the characteristics of the variable or database field you name.

If you reference a database field in the LIKE option, the database containing that field must be connected at both compile time and run time. Therefore, use the LIKE option with caution.

field-options

Specifies options for the temp-table field. Any options you specify override any options inherited through the LIKE option. This is the syntax for field-options:
DEFINE WORK-TABLE statement

Note: You cannot specify a BLOB field, a CLOB field, or an indeterminate array field in a work-table.

For a description of each option, see the DEFINE VARIABLE statement.

Example

The r-wrkfil.p procedure accumulates all balances by state and stores that information for display later. The procedure uses a work table to accomplish this task.

The r-wrkfil.p procedure defines the work table showsales. The work table contains the three fields named region, state, and tot-sales. These fields have all the same characteristics (except labels) as the Customer.SalesRegion, Customer.State, and Customer.Balance fields, respectively.

The first FOR EACH loop in the r-wrkfil.p procedure sorts Customers by state. Then it accumulates the balances for each Customer by state. When the procedure finds the last Customer in a state, it creates a showsales record for that state. The procedure assigns information to the fields in the showsales record. After looking at each Customer, the procedure continues to the next FOR EACH statement.

The second FOR EACH statement in the r-wrkfil.p procedure uses the information stored in the showsales table. Because you treat a work table within a procedure the same way you treat a database table, you can perform the same work with the showsales table that you can with a database table.
DEFINE WORK-TABLE statement

You cannot perform a unique find on a work table. When finding records in a work table, you must use FIRST, LAST, NEXT, or PREV with the FIND statement, unless you are finding a record using its ROWID.

You cannot define a field in a work table with the MEMPTR data type, but you can define a work table field as ROWID or RAW.

You cannot define shared objects, work tables, or temp-tables within an internal procedure, a method in a class, or a user-defined function.

ABL disregards the following options when used in conjunction with a work table:

- The VALIDATE option on a DELETE statement
- The SHARE-LOCK, EXCLUSIVE-LOCK, and NO-LOCK options used with the FIND or FOR statements
- The NO-WAIT option on the FIND statement

When you use the AMBIGUOUS function in conjunction with a work table, the function always returns a value of FALSE.

Complete work table definitions must be included in a DEFINE SHARED WORK-TABLE statement and shared work tables must be defined identically.

These are the differences between work tables and regular database tables:

- The AVM does not use the OpenEdge database manager (and server for multi-user systems) when working with work tables.
- If you do not explicitly delete the records in a work table, the AVM discards those records, and the work table, at the end of the procedure that initially defined the work table.
- Users do not have access to each other’s work tables.

---

**r-wrkfil.p**

```plaintext
DEFINE WORK-TABLE showsales
FIELD region LIKE SaleRep.Region LABEL "Region"
FIELD state LIKE Customer.State LABEL "St"
FIELD tot-sales LIKE Customer.Balance COLUMN-LABEL "Total\!Sales".

FOR EACH Customer, SalesRep OF Customer BREAK BY Customer.State:
  IF LAST-OF(Customer.State) THEN DO:
    CREATE showsales.
    showsales.state = Customer.State.
    showsales.region = SalesRep.Region.
  END.
END.

FOR EACH showsales BREAK BY showsales.region BY showsales.state:
  IF FIRST-OF(showsales.region) THEN
    DISPLAY showsales.region.
  DISPLAY showsales.state tot-sales (TOTAL BY showsales.region).
END.
```

---

**Notes**

- You cannot perform a unique find on a work table. When finding records in a work table, you must use FIRST, LAST, NEXT, or PREV with the FIND statement, unless you are finding a record using its ROWID.

- You cannot define a field in a work table with the MEMPTR data type, but you can define a work table field as ROWID or RAW. 

- You cannot define shared objects, work tables, or temp-tables within an internal procedure, a method in a class, or a user-defined function.

- ABL disregards the following options when used in conjunction with a work table:

  - The VALIDATE option on a DELETE statement
  - The SHARE-LOCK, EXCLUSIVE-LOCK, and NO-LOCK options used with the FIND or FOR statements
  - The NO-WAIT option on the FIND statement

- When you use the AMBIGUOUS function in conjunction with a work table, the function always returns a value of FALSE.

- Complete work table definitions must be included in a DEFINE SHARED WORK-TABLE statement and shared work tables must be defined identically.

- These are the differences between work tables and regular database tables:

  - The AVM does not use the OpenEdge database manager (and server for multi-user systems) when working with work tables.
  - If you do not explicitly delete the records in a work table, the AVM discards those records, and the work table, at the end of the procedure that initially defined the work table.
  - Users do not have access to each other’s work tables.
Because you cannot index a work table, the AVM uses the following rules for storing records in a work table:

- If you create a series of work table records without doing any other record operations, the AVM orders the newly created records in the order they were entered.
- If you use the FIND PREV statement at the beginning of a work table and then create a work table record, the AVM stores that record at the beginning of the work table.
- When you use the FIND statement to find a work table record and then use the CREATE statement to create a new work table record, the AVM stores that new record after the record you just found.

Data handling statements that cause the AVM to automatically start a transaction for a regular table will not cause the AVM to automatically start a transaction for a work table. To start a transaction for operations involving a work table, Use the TRANSACTION keyword.

Work tables are private:

- Even if two users define work tables with the same name, the work tables are private; one user cannot see records the other user has created.
- If two procedures run by the same user define work tables with the same name, the AVM treats those work tables as two separate tables unless the SHARED option is included in both procedures.

DEFINE SHARED WORK-TABLE does not automatically provide a shared buffer. If you want to use a shared buffer with a shared work table, you must define that buffer.

Work table records are built in 64-byte sections. Approximately the first 60 bytes of each record are taken up by record specification information (or a record header). That is, if a record is 14 bytes long, it will be stored in two 64-byte sections, using the first 60 bytes as a record header. If the record is 80 bytes long, it will fit into three 64-byte sections. The first part contains 60 bytes of header information plus the first 4 bytes of the record. The second section contains 64 bytes of the record. And the last section contains the remaining record bytes.

The NO-UNDO option in a work table definition overrides a transaction UNDO for CREATE, UPDATE, DELETE, and RELEASE statements accessing the work table, regardless of whether these statements are executed before or during the transaction block that is undone.

A transaction UNDO overrides a FIND statement accessing a work table defined with the NO-UNDO option, regardless of whether the find is executed before or during the transaction that is undone.

You should use the CASE-SENSITIVE option only when it is important to distinguish between uppercase and lowercase values entered for a character field. For example, use CASE SENSITIVE to define a field for a part number that contains mixed upper case and lowercase characters.

A SHARED work table remains in scope for an instance of a persistent procedure until the instance is deleted. This is true even if the original procedure that defined the work table as NEW SHARED goes out of scope while the procedure instance remains persistent.
DEFINE WORKFILE statement

If a trigger or internal procedure of a persistent procedure executes an external subprocedure that defines a SHARED work table, ABL includes the persistent procedure in the resolution of the corresponding NEW SHARED work table as though the procedure were on the procedure call stack.

- You cannot define a SHARED or NEW SHARED work table in a class definition (.cls) file. If you do, ABL generates a compilation error.
- You can specify a join between a temp-table or work table and any appropriate table using the OF keyword. The two tables must contain a commonly named field that participates in a unique index for at least one of the tables. For more information on table joins see the Record phrase reference entry.
- See OpenEdge Getting Started: ABL Essentials for information on work tables and temp-tables.

See also { } Argument reference, { } Include file reference, Class-based data member access, CREATE statement, DEFINE BUFFER statement, DEFINE TEMP-TABLE statement, FIND statement, Format phrase, RUN statement

DEFINE WORKFILE statement

See the DEFINE WORK-TABLE statement reference entry.

This statement is supported only for backward compatibility. Use the DEFINE TEMP-TABLE statement, instead.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
DEFINE { [ [ NEW ] SHARED ] | [ PRIVATE ] } { WORK-TABLE | WORKFILE } work-table-name
[ NO-UNDO ]
[ LIKE tablename ]
[ FIELD field-name
  { AS data-type
    | LIKE field
  }
  [ field-options ]
] ... 
```

**DEFINED preprocessor function**

Returns the status of a preprocessor name or include file argument name as an INTEGER value. You can use the DEFINED function only within a preprocessor &IF expression.
DELETE statement

Removes a record from a record buffer and from the database.

Data movement

```
DELETE record
[ VALIDATE ( condition , msg-expression ) ]
[ NO-ERROR ]
```

`record`

The name of a record buffer. You can delete a record only after it has been put into a record buffer by a CREATE, FIND, FOR EACH, or INSERT statement.

If you define an alternate buffer for a table, you can delete a record from that buffer by using the name of the buffer with the DELETE statement.
To delete a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

**VALIDATE** ( condition, msg-expression )

Use the VALIDATE option to specify a logical value that allows the deletion of a record when TRUE, but does not allow the deletion of a record when FALSE.

The condition is a Boolean expression (a constant, field name, variable name, or expression) with a value of TRUE or FALSE.

The msg-expression is the message you want to display if the condition is FALSE. You must enclose msg-expression in quotation marks ("").

You can also describe delete validation criteria for a table in the Data Dictionary. To suppress the Data Dictionary delete validation criteria for a table, use the VALIDATE option as follows:

```
VALIDATE(TRUE,"")
```

If you use the DELETE statement to delete a record in a work table, the AVM disregards any VALIDATE option you use with the DELETE statement.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.
- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.
- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.
Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Examples**

The `r-delet.p` procedure deletes all the records in the Customer table.

```
r-delet.p

FOR EACH Customer:
    DELETE Customer.
END.
```

The `r-delet2.p` procedure prompts the user for a Customer number and then displays the name of that Customer. It then prompts the user to press y to confirm the deletion of the Customer record. The user’s response is stored in the del variable. If the value of the del variable is y, the procedure deletes the Customer record.

```
r-delet2.p

DEFINE VARIABLE del AS LOGICAL NO-UNDO FORMAT "y/n".

REPEAT:
    PROMPT-FOR Customer.CustNum.
    FIND Customer USING Customer.CustNum.
    DISPLAY Customer.Name.
    del = NO.
    UPDATE del LABEL "Enter ""y"" to confirm delete".
    IF del THEN DELETE Customer.
END.
```
The `r-delval.p` procedure prompts the user for a Customer number. The procedure displays
the name of the Customer and prompts the user: Do you want to delete this Customer? If the
user answers no, the procedure prompts the user for another Customer number. If the user
answers yes, the procedure checks whether the Customer has orders, using the VALIDATE
option. If they do have orders, the procedure displays this message: This Customer has
outstanding orders and cannot be deleted. If the Customer has no orders, the procedure deletes
the Customer.

```
define variable ans as logical no-undo.
repeat with 1 down:
  prompt-for customer.custnum.
  find customer using customer.custnum.
  display customer.name.
  ans = no.
  display "Do you want to delete this Customer?"
  with frame f-query.
  update ans with frame f-query no-labels.
  if ans then
    delete customer validate(not(can-find(order of customer)),
      "This Customer has outstanding orders and cannot be deleted.").
  end.
```

**Notes**

- When you run procedures that delete large numbers of records (for example, a month-end
table purge), the process runs much faster if you use the No Crash Protection (-i) parameter
in single-user mode. (You must back up your database before using this option.) See
  *OpenEdge Deployment: Startup Command and Parameter Reference* for more
  information on startup parameters.

- Deleting records does not change the amount of space the database takes up on the disk.
The AVM re-uses ROWIDs. It does not delete the ROWID when a record is deleted. To
  recover disk space, you must dump and reload your database.

- The DELETE statement causes any related database DELETE triggers to execute. All
  DELETE triggers execute before the AVM actually deletes the record. While a DELETE
  trigger is executing, all FIND requests for the record (even within the trigger) fail, as if the
  record were already deleted. If a DELETE trigger fails (or executes a RETURN ERROR
  statement), the corresponding record is not deleted.

- If a table has both a DELETE trigger and delete VALIDATION, the DELETE trigger
  executes before the validation is performed.

- If you have previously retrieved record with a field list, the DELETE statement rereads
  the complete record before deleting it.

**See also** CREATE statement, FIND statement, FOR statement, INSERT statement

**DELETE ALIAS statement**

Deletes an alias from the alias table.
DELETE ALIAS { alias | VALUE ( expression ) }

alias

An existing alias. It can be an unquoted string or a quoted string.

VALUE ( expression )

A character-string expression that evaluates to an existing alias.

Example

This procedure deletes the alias myalias from the alias table:

```
DELETE ALIAS myalias.
```

Notes

- If a precompiled program requires an alias and you delete that alias, the program will not run.
- If you try to delete a nonexistent alias, nothing happens.

`ALIAS function`, `CONNECT statement`, `CONNECTED function`, `CREATE ALIAS statement`, `CREATE CALL statement`, `DATASERVERS function`, `DBCODEPAGE function`, `DBCOLLATION function`, `DBRESTRICTIONS function`, `DBTYPE function`, `DBVERSION function`, `DISCONNECT statement`, `FRAME-DB function`, `LDBNAME function`, `NUM-DBS function`, `PDBNAME function`, `SDBNAME function`

DELETE OBJECT statement

Deletes an object such as a widget, a procedure, a server, a socket, or an instance of a class. Deleting the object causes all allocated resources associated with the object to be returned to the system (except when otherwise noted).

Syntax

```
DELETE OBJECT { handle | object-reference } [ NO-ERROR ]
```

handle

A handle to an ABL handle-based object. The handle argument must be a variable of type HANDLE and must contain a valid handle.

If the handle parameter refers to a widget, the DELETE OBJECT statement is a synonym for the DELETE WIDGET statement.

If the handle parameter refers to a persistent procedure handle or proxy persistent procedure handle, the DELETE OBJECT statement is a synonym for the DELETE PROCEDURE statement. This statement deletes a local persistent procedure handle immediately. For a proxy persistent procedure handle, this statement deletes the handle immediately unless there is an outstanding asynchronous request on this handle (handle:ASYNC-REQUEST-COUNT is greater than zero (0)). If
handle:ASYNC-REQUEST-COUNT is greater than zero (0), this statement raises the ERROR condition. Otherwise, the statement also sends a request to the AppServer to delete the corresponding remote persistent procedure on the AppServer. If the AppServer is executing any asynchronous requests ahead of it, the AVM queues the delete request (as with any asynchronous remote request) until the AppServer is available to handle it.

Note: This same behavior occurs if the remote procedure deletes itself (using DELETE...THIS-PROCEDURE) on the AppServer.

For more information on remote persistent procedures, see *OpenEdge Application Server: Developing AppServer Applications*.

If the handle parameter refers to a server handle, the DELETE OBJECT statement:

- Checks that the handle parameter refers to a valid server handle, and that the handle parameter’s CONNECTED attribute is FALSE (no AppServer is connected to it). If one of these checks fails, the statement raises the ERROR condition.

- Deletes the handle immediately, if the server handle is valid, unless there is an outstanding asynchronous request on this handle (handle:ASYNC-REQUEST-COUNT is greater than zero (0)). If there is an outstanding asynchronous request, this statement raises the ERROR condition.

Deleting a server handle removes the handle from the server handle chain of the SESSION system handle, and resets SESSION:FIRST-SERVER and SESSION:LAST-SERVER if necessary. This also deletes all of the asynchronous request handles associated with the server and then deletes the server object.

If handle refers to an asynchronous request handle, the DELETE OBJECT statement takes one of the following actions:

- If the handle:COMPLETE attribute is FALSE, it raises the ERROR condition.

- If the handle:COMPLETE attribute is TRUE, it removes handle from the chain of asynchronous request handles referenced by the FIRST-ASYNC-REQUEST and the LAST-ASYNC-REQUEST attributes of the server handle, and deletes handle.

If this is a socket handle, the application must disconnect the socket from a port using the DISCONNECT( ) method before a socket object can be deleted. The DELETE OBJECT statement raises ERROR if an application deletes a socket object that is still associated with a port.

If this is a server socket handle, the application must call DISABLE-CONNECTIONS( ) before a server socket object can be deleted. The DELETE OBJECT statement raises ERROR if an application deletes a server socket object that is still listening for connections.

**object-reference**

An object reference to a class instance. The object reference argument must be an ABL object reference variable, such as one defined using the DEFINE VARIABLE statement or the DEFINE PARAMETER statement with the CLASS option, and it must contain a valid object reference.
Note: You can validate an object reference by using the VALID-OBJECT function.

When you delete a class instance, the AVM invokes the destructor for the class and the destructor for each class in its inherited class hierarchy, if any. The destructor can be used for freeing resources allocated to the object when the object is deleted. At this time, the object context goes out of scope. In addition, the object is removed from the list of valid ABL class instances (session object chain) referenced by the FIRST-OBJECT attribute or LAST-OBJECT attribute of the SESSION system handle.

If you do not delete a class instance and you have not turned off automatic garbage collection using the No Garbage Collection (-nogc) startup parameter, the instance is deleted when there are no more references to it.

OpenEdge includes a performance tuning feature for ABL class-based applications that controls how the AVM deletes objects. The Re-usable Objects Cache (-reusableObjects) startup parameter specifies the number of deleted class objects that the AVM stores for later re-initialization. By default, -reusableObjects is set to 25. When you use -reusableObjects, the AVM transfers the deleted object for most ABL classes to a re-usable objects cache. If your application causes the AVM to instantiate the same class later, the stored object is re-initialized and removed from the cache. The re-initialized object has a new UUID and the same initial data as a new instance of the class. The re-use of the object saves much of the overhead of instantiating a class.

For most ABL classes, the AVM transfers the deleted object to a re-usable objects cache. The re-usable object cache provides a means for you to tune the performance of ABL class-based applications. If your application causes the AVM to instantiate the same class later, the stored object is re-initialized and removed from the cache. The re-initialized object has a new UUID and the same initial data as a new instance of the class. The re-use of the object saves much of the overhead of instantiating a class.

Note: The cache does not store .NET classes, .NET-derived ABL classes, classes with static elements, or classes compiled during your session.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option, you can:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.
- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the
DELETE OBJECT statement

ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE(message-num) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option are:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, an ON ERROR phrase, or an UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object are used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

Notes

- When a temp-table object is passed as a TABLE-HANDLE output parameter, the deletion of the object following the DELETE OBJECT statement is postponed until the procedure goes out of scope. When the procedure returns, the TABLE-HANDLE is created, receives a copy of the original temp-table, and is then returned.

- The OUTPUT TABLE-HANDLE parameter creates a TEMP-TABLE in the target procedure, which is added to the SESSION widget-pool. You must use the DELETE OBJECT statement to delete this TEMP-TABLE when it is no longer needed, or you will create a memory leak.

- Using automatic garbage collection (the default), the AVM deletes each class instance when no references to the object exist other than on the session object chain (accessible using the FIRST-OBJECT attribute or LAST-OBJECT attribute of the SESSION system handle). When a class instance is garbage collected, its destructor runs as if you deleted the object using DELETE OBJECT. As with DELETE OBJECT, automatic garbage collection stores the deleted object in a re-usable object cache.
• You can turn off automatic garbage collection using the No Garbage Collection (-nogc) startup parameter. However, if you do so, you must decide when to use this statement to delete each class instance you no longer need. Furthermore, a class instance that has no other references still remains in memory. You must locate it by walking the session object chain and then delete it.

• The Re-usable Object Cache (-reusableObjects) startup parameter controls how many deleted class-based objects are cached. By default, the parameter is set to 25. You can disable this feature by setting the parameter value to zero. When the cache is full and you delete another object, the AVM uses a least-recently used scheme to make room in the cache.

• The AVM only uses an object in the re-usable object cache to re-instantiate the same class. It cannot use an object to instantiate another class in the same inheritance hierarchy. For example, Class B inherits Class A and is inherited by Class C. If the cache contains an instance of Class B, the AVM cannot use that object to help instantiate either an instance of Class A or Class C. The AVM can only use that object for a new instance of Class B.

• If you invoke DELETE OBJECT from within a class constructor, specifying the THIS-OBJECT system reference for object-reference, class instantiation stops, and the AVM invokes the destructor for the instantiating class and for each class in its class hierarchy where the constructor has already completed execution. After all destructors have completed, control returns to the statement following the statement that instantiated the class using the NEW function (classes), the NEW statement, or the DYNAMIC-NEW statement. When control returns from the context of a NEW statement or a DYNAMIC-NEW statement, the data element set to receive the object reference to the failed class instantiation receives the Unknown value (?).

• When you invoke DELETE OBJECT from within a class constructor, the object is stored to the re-usable object cache. By the time the instantiation reaches a constructor, the object data stored in the cache is already in memory. Even though the current instantiation never completes, the AVM can use the object data to instantiate another instance of the class at a later time without problems.

• If you need to terminate class instantiation within a constructor, Progress Software Corporation recommends that you use a RETURN ERROR or a THROW (as in the RETURN statement or UNDO statement, respectively). This has the same effect as using the DELETE OBJECT THIS-OBJECT statement and also raises ERROR on the statement that attempts to instantiate the class. This allows your application to handle the uninstantiated class condition using ABL error handling options, such as the CATCH statement or the NO-ERROR option on many statements.

• For more information on working with asynchronous remote procedures and event procedures, see OpenEdge Application Server: Developing AppServer Applications.

• For more information on working with socket and server socket objects, see OpenEdge Development: Programming Interfaces.

• For more information on working with class instances, see OpenEdge Development: Object-oriented Programming.

• Automatic garbage collection works for .NET objects, or for ABL objects that derive from .NET objects, similar to how it works for pure ABL class instances. However, .NET objects and the .NET components of an ABL-derived .NET object are also managed
separately by .NET garbage collection. Thus, the release of memory held by a .NET object or an ABL-derived .NET object depends on both ABL and .NET garbage collection.

- For a .NET form object, you can typically invoke its `Close()` method or the `System.Windows.Forms.Application:Exit()` method (for non-modal forms) to both close the form and delete the associated object, making it available for .NET garbage collection. One instance where a form is not deleted using the `Close()` method is when a non-modal form is an invisible child form of a multiple-document interface (MDI). In this case, you must also invoke the DELETE OBJECT statement on the associated object reference, or otherwise remove all references to the form, to make the form available for .NET garbage collection.

- In a .NET event handler for the `FormClosing` event, if you do delete object references, do not delete the object reference to the form (sender) that published the `FormClosing` event. Otherwise, this causes the `FormClosing` event to be published a second time for the same form. If you need to delete the sender of an event associated with the closing of a .NET form, execute the DELETE OBJECT statement on the sender in an event handler for the `FormClosed` event of the form. However, note that with garbage collection, you typically do not need to delete any object references in a .NET event handler.

- In ABL, the .NET `Dispose()` method is also available for freeing resources held by a .NET object in order to more quickly enable garbage collected on the object. Typically, using automatic garbage collection or the DELETE OBJECT statement is sufficient to ensure that .NET frees all resources held by the affected object when it is ready to do so. However there is one exception when you must use the `Dispose()` method. This is on a .NET modal form object (dialog box) that is open and then closed either when a user clicks the Close(\x) button in the upper right-hand corner of the dialog box or when your application sets the `DialogResult` property on the form. In these cases, you must call the `Dispose()` method on the form object in order to enable garbage collection on the form. For more information, see the WAIT-FOR statement (.NET and ABL) reference entry.

DELETE PROCEDURE statement, DELETE WIDGET statement, DESTRUCTOR statement, ERROR-STATUS system handle, THIS-OBJECT system reference, RETURN statement, UNDO statement

### DELETE PROCEDURE statement

Deletes an instance of a persistent procedure. The persistent procedure can be local or remote.

#### Syntax

```plaintext
DELETE PROCEDURE proc-handle [ NO-ERROR ]
```

- `proc-handle` - The handle of a local or remote persistent procedure. This is a variable, field, or expression of type HANDLE that contains a valid persistent procedure handle.

For a proxy persistent procedure handle, this statement deletes the handle immediately unless there is an outstanding asynchronous request on this handle (`handle:ASYNC-REQUEST-COUNT` is greater than zero (0)). If `handle:ASYNC-REQUEST-COUNT` is greater than zero (0), this statement raises the
DELETE PROCEDURE statement

ERROR condition. Otherwise, the statement also sends a request to the AppServer to delete the corresponding remote persistent procedure on the AppServer. If the AppServer is executing any asynchronous requests ahead of it, the AVM queues the delete request (as with any asynchronous remote request) until the AppServer is available to handle it.

**Note:** This same behavior occurs if the remote procedure deletes itself (using DELETE...THIS-PROCEDURE) on the AppServer.

For more information on remote persistent procedures, see *OpenEdge Application Server: Developing AppServer Applications*.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.
• When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

• If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

Example
When you run the following procedure non-persistently, the procedure creates a persistent instance of itself in addition to the non-persistent instance, creating two query windows for the Customer table. Choosing the Cancel button in either window causes the instance that owns that window to terminate. If the instance you terminate is persistent, the Cancel button runs an internal procedure that executes the DELETE PROCEDURE statement for that instance as specified by the THIS-PROCEDURE system handle.

```r-delprc.p
(1 of 2)
```

```plaintext
DEFINE QUERY custq FOR Customer.
DEFINE BROWSE custb QUERY custq
   DISPLAY name balance phone WITH 10 DOWN.
DEFINE BUTTON bName LABEL "Query on Name".
DEFINE BUTTON bBalance LABEL "Query on Balance".
DEFINE BUTTON bCancel LABEL "Cancel".
DEFINE FRAME CustFrame custb SKIP bName bBalance bCancel.
DEFINE VARIABLE custwin AS HANDLE.
ON CHOOSE OF bName IN FRAME CustFrame DO:
   custwin:TITLE = "Customers by Name".
   OPEN QUERY custq FOR EACH Customer BY Customer.Name.
END.

ON CHOOSE OF bBalance IN FRAME CustFrame DO:
   custwin:TITLE = "Customers by Balance".
   OPEN QUERY custq FOR EACH Customer BY Customer.Balance DESCENDING.
END.

IF THIS-PROCEDURE:PERSISTENT THEN DO:
   THIS-PROCEDURE:PRIVATE-DATA = "Customer Browse".
   CREATE WIDGET-POOL.
END.
```
DELETE PROCEDURE statement

Notes

• To be valid for deletion, proc-handle must reference an active persistent procedure. You can use the VALID-HANDLE function and PERSISTENT procedure attribute to check the validity of proc-handle. Thus, both VALID-HANDLE(proc-handle) and proc-handle:PERSISTENT must be TRUE to delete the specified procedure. If either of these expressions is FALSE, the DELETE PROCEDURE statement raises the ERROR condition.

• When you delete a persistent procedure instance, its context goes out of scope and all allocated resources are returned to the system. In addition, it is removed from the chain of persistent procedures referenced by the FIRST-PROCEDURE and LAST-PROCEDURE attributes of the SESSION system handle.

• If you delete a persistent procedure instance while executing statements within that procedure, the DELETE PROCEDURE statement pends until the largest executing block in the persistent procedure terminates. Thus, if the DELETE PROCEDURE occurs while the main procedure block is executing (when the persistent procedure is called), the procedure is deleted when the procedure returns (as if it were non-persistent). If the DELETE PROCEDURE occurs during execution of a trigger or execution of an internal procedure that is called from another external procedure, the procedure is deleted after the trigger block or internal procedure returns. Note that while the delete is pending, the persistent procedure remains valid in the persistent procedure chain.

• The DELETE PROCEDURE statement disconnects any local buffers established by the procedure. In addition, any buffers passed as parameters to a persistent procedure are treated as local buffers. While all cursor positioning established on these buffers by the persistent procedure is lost, there is no affect on the original buffers passed as parameters from the caller. Note that all buffers are validated before being disconnected (which might cause database write triggers to execute). If the validation fails, the DELETE PROCEDURE statement raises the ERROR condition and pends the deletion until the validation succeeds and all database write triggers have completed.

CREATE WINDOW custwin ASSIGN
   TITLE = IF THIS-PROCEDURE:PERSISTENT THEN
   "Persistent Customer Browser" ELSE "Customer Browser"
   SCROLL-BARS = FALSE
   MAX-HEIGHT-CHARS = FRAME CustFrame:HEIGHT-CHARS
   MAX-WIDTH-CHARS = FRAME CustFrame:WIDTH-CHARS.

THIS-PROCEDURE:CURRENT-WINDOW = custwin.
ENABLE ALL WITH FRAME CustFrame.
IF THIS-PROCEDURE:PERSISTENT THEN DO:
   ON CHOOSE OF bCancel IN FRAME CustFrame DO:
      RUN destroy-query.
   END.
END.
ELSE DO:
   RUN r-delprc.p PERSISTENT.
   WAIT-FOR CHOOSE OF bCancel IN FRAME CustFrame.
   DELETE WIDGET custwin.
END.

PROCEDURE destroy-query:
   DELETE PROCEDURE THIS-PROCEDURE.
   DELETE WIDGET-POOL.
END PROCEDURE.
DELETE WIDGET statement

- For more information on working with asynchronous remote procedures and event procedures, see *OpenEdge Application Server: Developing AppServer Applications*.

See also RUN statement, THIS-PROCEDURE system handle, VALID-HANDLE function

---

**DELETE WIDGET statement**

Deletes one or more dynamic widgets.

**Syntax**

```
DELETE WIDGET handle [ handle ] ...
```

`handle`

The handle of a dynamic widget.

**Example**

In the following example, the DELETE WIDGET statements deletes the dynamic button that you select:
DELETE WIDGET statement

**Notes**

- If you do not explicitly delete a dynamically created widget, it is deleted when its widget pool is deleted. If you do not create a new unnamed widget pool and do not explicitly specify a named widget pool when you create the widgets, all dynamic widgets are placed in the session pool. The session pool is not deleted until the ABL session that created it ends.

- If `handle` refers to a control-frame, any ActiveX control associated with the widget is also deleted. For more information on ActiveX support in ABL, see *OpenEdge Development: Programming Interfaces*.

- For SpeedScript, use with buffer-field, buffer-object, buffer, and query-object handles.

**See also**

CREATE widget statement
DELETE WIDGET-POOL statement

Deletes a defined widget pool.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
DELETE WIDGET-POOL [ pool-name ] [ NO-ERROR ]
```

*pool-name*

The name of a defined dynamic widget pool. If you omit *pool-name*, the statement deletes the unnamed pool most recently created in the current or a calling procedure or class-based method.

*NO-ERROR*

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the **ERROR-STATUS** system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the **NO-ERROR** option:

- Check the **ERROR-STATUS:ERROR** attribute to see if the AVM raised the **ERROR** condition.
- Check if the **ERROR-STATUS:NUM-MESSAGES** attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block **without** a CATCH end block treat errors as warnings and do not raise **ERROR**, do not set the **ERROR-STATUS:ERROR** attribute, but do add messages to the **ERROR-STATUS** system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block **with** a CATCH end block raise **ERROR** and add messages to the error object generated by the AVM. In this case, the AVM does not update the **ERROR-STATUS** system handle.
- Use **ERROR-STATUS:GET-MESSAGE**(*message-num*) to retrieve a particular message, where *message-num* is 1 for the first message.

If the statement does not include the **NO-ERROR** option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the **NO-ERROR** option:

- **NO-ERROR** does not suppress errors that raise the **STOP** or **QUIT** condition.
- A CATCH statement, which introduces a CATCH end block, is analogous to a **NO-ERROR** option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error
object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Example**

The following example creates a named widget pool and lets you add buttons to it. When you choose Delete Buttons, the widget pool is deleted. (Therefore all the buttons in the pool are also deleted.) Similarly, when you choose Quit to exit the procedure the widget pool is also deleted. Because the pool is persistent, it remains allocated for the rest of your session if you do not delete it.
DELETE WIDGET-POOL statement

Notes

- When you delete a widget pool, all widgets in that pool are automatically deleted.

- If you do not delete a non-persistent widget pool, it is deleted when the procedure or method that created it ends. If you do not delete a persistent widget pool, it is deleted when the session ends.

- All named widget pools are globally scoped. While a named widget pool is allocated, any procedure or method within the same process can access that widget pool. If you try to delete a named widget pool that does not exist, the AVM raises the ERROR condition.

See also

CREATE WIDGET-POOL statement, DELETE WIDGET statement
DESTRUCTOR statement

Defines a destructor for a class. A destructor is a special type of method that the AVM invokes when an instance of the class is deleted, either manually using the DELETE OBJECT statement or automatically through garbage collection.

Note: This statement is applicable only when used in a class definition (.cls) file.

Syntax

```
DESTRUCTOR [ PUBLIC ] class-name () :

   destructor-body
```

[ PUBLIC ]

Specifies the access mode for the destructor. For destructors, this is always PUBLIC by default.

As a PUBLIC resource, a destructor can be accessed indirectly by the defining class, any of its inheriting classes, and any class or procedure that instantiates the class object (that is, through an object reference), either by deleting the object instance using the DELETE OBJECT statement or as a result of garbage collection.

class-name

The name of the class this method destroys. This name must match the class name portion of the type name for the class (that is, the name of the class definition file excluding the .cls extension and any package path information).

destructor-body

The body of the destructor definition. Define the destructor body using the following syntax:

```
   method-logic

   END [ DESTRUCTOR ] .
```

method-logic

The logic of the destructor, which can contain any ABL statements currently allowed within a PROCEDURE block including class-related statements, but excluding the RETURN ERROR statement. The method’s logic must not reference, either directly or indirectly, statements that block for input (namely, the CHOOSE, INSERT, PROMPT-FOR, READKEY, SET, UPDATE, and WAIT-FOR statements).

This method typically contains logic to release system resources used by the class instance, for example, by executing the DELETE OBJECT statement for
handle-based objects created by the class or by invoking the Dispose( ) method on .NET objects created by the class. However, note that if the ABL class inherits from a .NET class, you cannot reliably access members of the .NET super class from your class destructor, because .NET might already have garbage collected it.

END [ DESTRUCTOR ]

Specifies the end of the destructor body definition. You must end the destructor body definition with the END statement.

Example

The following example shows the definition of a destructor:

```
DESTRUCTOR PUBLIC CustObj( ):
    EMPTY TEMP-TABLE ttCust.
END DESTRUCTOR.
```

Notes

- You can terminate a DESTRUCTOR statement with either a period (.) or a colon (:), but typically use a colon (:).
- A destructor has no parameters and no return value.
- You never explicitly invoke the destructor to delete a class instance. The method is implicitly invoked when the object is destroyed manually by the DELETE OBJECT statement or automatically as a result of garbage collection.
- The AVM also invokes the destructor of a given class if some constructor in the same class hierarchy raises ERROR during object instantiation and the constructor for the given class has already completed execution during this instantiation.
- If your application does not require it, you do not need to define a destructor for the class. ABL provides a default destructor for classes that do not define one.

CLASS statement, CONSTRUCTOR statement, DELETE OBJECT statement

DICTIONARY statement

Runs the OpenEdge Data Dictionary.

Note: Does not apply to SpeedScript programming.

Syntax

```
DICTIONARY
```

Example

This procedure runs the Data Dictionary if the user answers yes to a prompt:
Notes

- The DICTIONARY statement is equivalent to RUN dict.p: it runs the ABL procedure called dict.p. The AVM uses the regular search rules to find the dictionary procedure. The dictionary procedure is part of the ABL system software.
- The AVM Query/Run-time provides a restricted version of the Data Dictionary.
- For more information on the Data Dictionary, see its on-line help.

DISABLE statement

Disables input for one or more field-level and child frame widgets within a frame that were previously enabled with the ENABLE statement. Disabling a widget prevents the user from providing input to the widget, but does not remove it from the display.

Syntax

DISABLE [ UNLESS-HIDDEN ]
{ ALL [ EXCEPT field ... ]
  | { field [ WHEN expression ] } ...
} { [ frame-phrase ] }

UNLESS-HIDDEN

Restricts DISABLE to fields whose HIDDEN attribute is FALSE.

ALL [ EXCEPT field ... ]

Specifies that all field-level widgets for a frame should be disabled, except those that you optionally specify.

field [ WHEN expression ]

A field-level widget to be disabled. If you use the WHEN option, then the field is disabled only if expression is TRUE when the DISABLE statement is executed. The expression must evaluate to a LOGICAL value.

frame-phrase

The frame that contains the widgets to disable. If you omit frame-phrase, the default frame for the current block is assumed.

You cannot use the IN WINDOW option of the frame phrase within a DISABLE statement. For more information on frame-phrase, see the Frame phrase reference entry.
In the following example, the CustNum field and the Quit button are initially active. When you press GO in the CustNum field, that field becomes disabled and the Save and Undo buttons and the CreditLimit field are enabled. If you choose either the Save or Undo button, those buttons and the CreditLimit field are again disabled and the CustNum field is enabled again.

```
DEFINE VARIABLE ok AS LOGICAL NO-UNDO.
DEFINE BUTTON b_quit LABEL "Quit" AUTO-ENDKEY.
DEFINE BUTTON b_save LABEL "Save".
DEFINE BUTTON b_undo LABEL "Undo".

DEFINE FRAME butt-frame
  b_save b_undo b_quit
  WITH CENTERED ROW SCREEN-LINES - 1.

FORM Customer
  WITH FRAME cust-info SIDE-LABELS CENTERED
  TITLE "Update Customer Credit Limit".

ON CHOOSE OF b_save, b_undo IN FRAME butt-frame DO:
  DISABLE b_save b_undo WITH FRAME butt-frame.
  DISABLE Customer.CreditLimit WITH FRAME cust-info.
  ENABLE Customer.CustNum WITH FRAME cust-info.
  IF SELF:LABEL = "save" THEN
    ASSIGN FRAME cust-info Customer.CreditLimit.
  END.
  CLEAR FRAME cust-info NO-PAUSE.
  APPLY "ENTRY" TO Customer.CustNum IN FRAME cust-info.
END.

ON GO OF Customer.CustNum IN FRAME cust-info DO:
  FIND Customer USING Customer.CustNum EXCLUSIVE NO-ERROR.
  IF AVAILABLE Customer THEN DO:
    DISABLE Customer.CustNum WITH FRAME cust-info.
    ENABLE Customer.CreditLimit WITH FRAME cust-info.
    ENABLE ALL WITH FRAME butt-frame.
    DISPLAY Customer WITH FRAME cust-info.
  END.
  ELSE DO:
    MESSAGE "No Customer Record exist for Customer number"
    INPUT Customer.CustNum ", Please re-enter."
    VIEW-AS ALERT-BOX WARNING BUTTONS OK-CANCEL UPDATE OK.
    IF NOT ok THEN
      APPLY "CHOOSE" TO b_quit IN FRAME butt-frame.
    END.
  END.
END.

ENABLE Customer.CustNum WITH FRAME cust-info.
ENABLE b_quit WITH FRAME butt-frame.
WAIT-FOR CHOOSE OF b_quit IN FRAME butt-frame
  FOCUS Customer.CustNum IN FRAME cust-info.
```

If you invoke the DISABLE statement for the parent frame of a frame family, the field representation widgets and descendant frames owned by the parent frame are all disabled. However, the field representation widgets of the descendant frames remain enabled and appear sensitive, although they cannot accept input. To disable field representation widgets in the descendant frames and make them appear insensitive, you must invoke DISABLE statements for each of the descendant frames.

See also  ENABLE statement, WAIT-FOR statement (ABL only)
DISABLE TRIGGERS statement

Disables database triggers before you perform a dump or load procedure. You must have CAN-DUMP and CAN-LOAD permissions on the table for which you want to disable the triggers.

Syntax

DISABLE TRIGGERS FOR { DUMP | LOAD } OF table-name

[ ALLOW-REPLICATION ]

DUMP

Disabling triggers for DUMP disables the trigger associated with the FIND event for the named table.

LOAD

Disabling triggers for LOAD disables all triggers associated with the CREATE, WRITE, REPLICATION-CREATE, REPLICATION-WRITE, REPLICATION-DELETE, and ASSIGN events for the named table.

table-name

The name of the table for which you want to disable the triggers. You can name only one table.

ALLOW-REPLICATION

Tells DISABLE TRIGGERS to disable only CREATE, ASSIGN, and WRITE triggers, and not REPLICATION-CREATE, REPLICATION-DELETE, and REPLICATION-WRITE triggers. The DELETE trigger is not disabled.

For more information on database replication, see the reference entry for the RAW-TRANSFER statement, and OpenEdge Data Management: Database Administration.

Example

The following example lets you dump or load the contents of a database table. The procedure uses the DISABLE TRIGGERS statement to disable the appropriate triggers before each dump or load operation.

r-dstrig.p

```
DEFINE SUB-MENU file
  MENU-ITEM viewit LABEL "&View Data"
  MENU-ITEM dumpit LABEL "&Dump Data"
  MENU-ITEM loadit LABEL "&Load Data"
  MENU-ITEM exit LABEL "E&xit".

DEFINE MENU mbar MENUBAR
  SUB-MENU file LABEL "&File".

DEFINE BUTTON b_more LABEL "Next".
DEFINE BUTTON b_exit LABEL "Cancel".
```
DEFINE VARIABLE ix AS INTEGER NO-UNDO.

DEFINE FRAME cust-frame
    Customer.CustNum SKIP
    Customer.Name  SKIP
    Customer.Phone SKIP
    b_more b_exit
    WITH CENTERED SIDE-LABELS ROW 3.

DEFINE STREAM cust.

PAUSE 0 BEFORE-HIDE.

ON CHOOSE OF b_exit IN FRAME cust-frame DO:
    HIDE FRAME cust-frame NO-PAUSE.
    DISABLE ALL WITH FRAME cust-frame.
    LEAVE.
END.

ON CHOOSE OF b_more IN FRAME cust-frame DO:
    FIND NEXT Customer NO-LOCK NO-ERROR.
    IF NOT AVAILABLE(Customer) THEN
        RETURN.
        DISPLAY Customer.CustNum Customer.Name Customer.Phone
        WITH FRAME cust-frame.
    END.

ON CHOOSE OF MENU-ITEM viewit DO:
    ENABLE ALL WITH FRAME cust-frame.
    FIND FIRST Customer NO-LOCK NO-ERROR.
    DISPLAY Customer.CustNum Customer.Name Customer.Phone
    WITH FRAME cust-frame.
END.

ON CHOOSE OF MENU-ITEM dumpit DO:
    DISABLE TRIGGERS FOR DUMP OF Customer.
    ix = 1.
    SESSION:IMMEDIATE-DISPLAY = TRUE.
    OUTPUT STREAM cust TO "Customer.d".
    FOR EACH Customer NO-LOCK:
        EXPORT STREAM cust Customer.
        DISPLAY ix LABEL "Records Processed"
        WITH FRAME rec-info SIDE-LABELS ROW SCREEN-LINES / 2 CENTERED.
        ix = ix + 1.
        PROCESS EVENTS.
    END.
    SESSION:IMMEDIATE-DISPLAY = FALSE.
    OUTPUT STREAM cust CLOSE. /*
    APPLY "ENTRY" TO b_quit IN FRAME butt-frame. */
END.

IF NOT RETRY THEN
    ASSIGN
        CURRENT-WINDOW:MENUBAR = MENU mbar:HANDLE
        CURRENT-WINDOW:VISIBLE = TRUE.
WAIT-FOR CHOOSE OF MENU-ITEM exit.
DEFINE VARIABLE ix AS INTEGER NO-UNDO.

DEFINE FRAME cust-frame
  Customer.CustNum SKIP
  Customer.Name  SKIP
  Customer.Phone SKIP
  b_more b_exit
WITH CENTERED SIDE-LABELS ROW 3.

DEFINE STREAM cust.

PAUSE 0 BEFORE-HIDE.

ON CHOOSE OF b_exit IN FRAME cust-frame DO:
  HIDE FRAME cust-frame NO-PAUSE.
  DISABLE ALL WITH FRAME cust-frame.
  LEAVE.
END.

ON CHOOSE OF b_more IN FRAME cust-frame DO:
  FIND NEXT Customer NO-LOCK NO-ERROR.
  IF NOT AVAILABLE(Customer) THEN
    RETURN.
  END.
  DISPLAY Customer.CustNum Customer.Name Customer.Phone
  WITH FRAME cust-frame.
END.

ON CHOOSE OF MENU-ITEM viewit DO:
  ENABLE ALL WITH FRAME cust-frame.
  FIND FIRST Customer NO-LOCK NO-ERROR.
  DISPLAY Customer.CustNum Customer.Name Customer.Phone
  WITH FRAME cust-frame.
END.

ON CHOOSE OF MENU-ITEM dumpit DO:
  DISABLE TRIGGERS FOR DUMP OF Customer.
  ix = 1.
  SESSION:IMMEDIATE-DISPLAY = TRUE.
  OUTPUT STREAM cust TO "Customer.d".
  FOR EACH Customer NO-LOCK:
    EXPORT STREAM cust Customer.
    DISPLAY ix LABEL "Records Processed"
    WITH FRAME rec-info SIDE-LABELS ROW SCREEN-LINES / 2 CENTERED.
    ix = ix + 1.
    PROCESS EVENTS.
  END.
  SESSION:IMMEDIATE-DISPLAY = FALSE.
  OUTPUT STREAM cust CLOSE. /* APPLY "ENTRY" TO b_quit IN FRAME butt-frame. */
END.

IF NOT RETRY THEN
  ASSIGN
    CURRENT-WINDOW: MENUBAR = MENU mbar:HANDLE
    CURRENT-WINDOW: VISIBLE = TRUE.
  WAIT-FOR CHOOSE OF MENU-ITEM exit.
DEFINE VARIABLE ix AS INTEGER NO-UNDO.

DEFINE FRAME cust-frame

    ASSIGN
        CURRENT-WINDOW:MENUBAR = MENU mbar:HANDLE
        CURRENT-WINDOW:VISIBLE = TRUE.
WAIT-FOR CHOOSE OF MENU-ITEM exit.
Notes

- You also can disable database triggers from the Data Dictionary.
- Triggers disabled with the DISABLE TRIGGERS statement remain disabled for the duration of the procedure in which you issued the statement and any subprocedures.
- The OpenEdge Data Dictionary automatically disables the appropriate triggers during data dump and load operations.
- The Disable Delete Trigger (-disabledeltrig) startup parameter disables the DELETE trigger when ALLOW-REPLICATION is on for the DISABLE TRIGGERS statement or the DISABLE-LOAD-TRIGGER() buffer method. For more information about this parameter, see OpenEdge Deployment: Startup Command and Parameter Reference.

ON statement, TRIGGER PROCEDURE statement

DISCONNECT statement

Disconnects the specified database.

Syntax

```
DISCONNECT
   { logical-name | VALUE ( expression ) }
   [ NO-ERROR ]
```

logical-name

A logical database name. It can be an unquoted string or a quoted string. The logical-name is previously set, at startup or with a CONNECT statement, by using the Logical Database Name (-ld) parameter. If a logical name was not specified using the -ld parameter, then the physical database filename, without the .db suffix, is the default logical name.

VALUE (expression)

A character-string expression that evaluates to a logical database name.
Suppresses ABL errors or error messages that would otherwise occur and diverts them to the **ERROR-STATUS** system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the **ERROR-STATUS:ERROR** attribute to see if the AVM raised the ERROR condition.
- Check if the **ERROR-STATUS:NUM-MESSAGES** attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block **without** a CATCH end block treat errors as warnings and do not raise ERROR, do not set the **ERROR-STATUS:ERROR** attribute, but do add messages to the **ERROR-STATUS** system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block **with** a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the **ERROR-STATUS** system handle.
- Use **ERROR-STATUS:GET-MESSAGE( message-num )** to retrieve a particular message, where `message-num` is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.
- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the **ERROR-STATUS** system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.
- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the **ERROR-STATUS** system handle as normal.
- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the **ERROR-STATUS** system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.
Example

This procedure disconnects the database with logical name mydb:

```
r-discnt.p

DISCONNECT mydb.
```

Notes

- By default, the AVM disconnects all databases at the end of a session. The DISCONNECT statement, which explicitly disconnects a database, does not execute until all active procedures that reference the database end or stop.

- If a transaction is active for `logical-name`, DISCONNECT is deferred until the transaction completes or is undone. If a CONNECT statement for the same `logical-name` database is executed before the same transaction completes or is undone, then the pending CONNECT and DISCONNECT cancel each other and the database remains connected.

- When the database referred to by `logical-name` is disconnected, existing aliases for `logical-name` remain in existence. Later, if you connect to a database with the same `logical-name`, the same alias is still available.

DISPLAY statement

Moves data to a screen buffer and displays the data on the screen or other output destination. The AVM uses frames to display data. A frame describes how constant and variable data is arranged for display and data entry. You can let ABL construct default frames or you can explicitly describe frames and their characteristics.

Data movement

```
Database

Record buffer

Screen buffer
```
DISPLAY statement

Syntax

```
DISPLAY
{ [ STREAM stream | STREAM-HANDLE handle ] [ UNLESS-HIDDEN ] }
{ [ expression
      [ format-phrase ]
      [ ( aggregate-phrase ) ]
      WHEN expression
      [ @base-field ]
    ]
  | [ SPACE [ ( n ) ] ]
  | [ SKIP [ ( n ) ] ]
} ...
{ [ IN WINDOW window ] [ frame-phrase ] [ NO-ERROR ] }
```

```
DISPLAY
{ [ STREAM stream | STREAM-HANDLE handle ] [ UNLESS-HIDDEN ] }
record [ EXCEPT field ... ]
{ [ IN WINDOW window ] [ frame-phrase ] [ NO-ERROR ] }
```

```
DISPLAY
{ [ expression ... ]
  | [ record [ EXCEPT field ... ] ]
} WITH BROWSE browse [ NO-ERROR ]
```

STREAM stream

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream. See the DEFINE STREAM statement reference entry and the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams.

STREAM-HANDLE handle

Specifies the handle to a stream. If handle is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams and stream handles.

UNLESS-HIDDEN

Restricts DISPLAY to fields whose HIDDEN attribute is FALSE.

expression

Identifies a constant, field name, variable name, or expression that results in the value you want to display. This can also be the built-in field name, proc-text, that returns a character string of column values from a row returned by a stored procedure proc-text-buffer.
If *expression* is a simple field or variable, the AVM checks to see if that particular field or variable is used previously in the same frame. If it has, the AVM displays the field or variable in the same frame field as the earlier instance of that field or variable.

In array fields, array elements with constant subscripts are treated just as any other field. Array fields with no subscripts are expanded as though you had typed in the implicit elements.

**Note:** You cannot display elements of an unfixed indeterminate array parameter or variable. You can use the EXTENT statement to fix the number of elements in the array before displaying them. For more information, see the EXTENT statement reference entry.

If you reference `a[i]` in the same frame that you reference `a` or `a[constant]`, `a[i]` overlays the appropriate frame field based on the value of `i`. It is displayed in a new frame field for `a[i]`. For example.

### r-array.p

```verbatim
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
FOR EACH SalesRep:
   DO ix = 1 TO 12:
      SET SalesRep.MonthQuota[ix] WITH 1 COLUMN.
   END.
   DISPLAY SalesRep.MonthQuota WITH FRAME a COLUMN 40 ROW 3 1 COLUMN.
END.
```

Here, `month-quota[i]` is referenced in the same frame that `month-quota` is referenced. That is, line 5 references `month-quota[i]` and line 3 references `month-quota`. Both references use the same frame. Therefore, instead of creating a new frame field for `month-quota[i]`, the AVM uses the same frame fields created for the entire `month-quota` array.

In the next procedure, line 4 references only elements 1 and 2. Therefore, when the AVM tries to overlay `month-quota[i]` in line 6, there is only room for elements 1 and 2. The AVM returns an error after you enter data for those two elements.

### r-array2.p

```verbatim
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
FOR EACH SalesRep:
   DO ix = 1 TO 12:
      SET month-quota[ix] WITH 1 COLUMN.
   END.
   DISPLAY month-quota WITH FRAME a COLUMN 40 ROW 3 1 COLUMN.
END.
```

The following example shows a solution to that problem:
If you explicitly reference a\[ix\] in a FORM statement, regular array fields (month-quota[1] and month-quota[2] in this example) are not overlaid.

**format-phrase**

Specifies one or more frame attributes for a field, variable, or expression. For more information on **format-phrase**, see the Format phrase reference entry.

**aggregate-phrase**

Identifies one or more aggregate values to be calculated optionally based on a change in a break group. This is the syntax for **aggregate-phrase**:

```
{    AVERAGE
        | COUNT
        | MAXIMUM
        | MINIMUM
        | TOTAL
        | SUB-AVERAGE
        | SUB-COUNT
        | SUB-MAXIMUM
        | SUB-MINIMUM
        | SUB-TOTAL
} ... [ LABEL aggr-label ] [ BY break-group ] ...
```

For more information on **aggregate-phrase**, see the Aggregate phrase reference entry.

**WHEN** expression

Displays an item only when the expression used in the WHEN option has a value of TRUE. Here, **expression** is a field name, variable name, or expression whose value is logical.

**@** base-field

The **base-field** must be the name of a field or variable; it cannot be an expression or constant. The field or variable must be viewed as a fill-in or text widget on the display.

The AVM reserves enough space for the **base-field** to hold the longest format displayed there. All right-justified fields (numerics that do not use side labels) are right justified.
within the reserved area. The label is left or right justified according to the base-field. Whenever you enter data into the base-field, the AVM blanks out any characters to the left or right of the area used by the field being displayed.

The AVM underlines a screen area that is the longer of the base-field and the overlaying field. However, you can enter as many characters as there are spaces in the format of the field.

To determine the format to use for displaying the expression at the base-field, the AVM looks at the following and uses the first format that applies:

- An explicit Format phrase used with the expression.
- If the expression is a character string constant, a format that accommodates that string.
- If the data type of the expression matches that of the base-field, the format of the base-field.
- The standard format of the expression as if it were displayed without a base-field.

SPACE N [ ( n ) ]

Identifies the number (n) of blank spaces the AVM inserts after the displayed expression displays. The n can be 0. If the number of spaces is more than the spaces left on the current line of the frame, the AVM starts a new line and discards extra spaces. If you do not use this option or do not use n, the AVM inserts one space between items in the frame.

SKIP N [ ( n ) ]

Identifies the number (n) of blank lines the AVM needs to insert after the expression is displayed. The n can be 0. If you do not use this option, the AVM does not skip a line between expressions unless the expressions do not fit on one line. If you use the SKIP option but do not specify n, or if n is 0, the AVM starts a new line unless it is already at the beginning of a new line.

IN WINDOW window

Identifies the window where the expression is displayed. The expression window must evaluate to the handle of a window.

frame-phrase

Specifies the overall layout and processing properties of a frame. For more information on frame-phrase, see the Frame phrase reference entry.

record

Identifies the name of the record you want to display. Naming a record is shorthand for listing each field individually. This can also be the built-in buffer name, proc-text-buffer, that returns each row retrieved by a stored procedure.

To display a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.
DISPLAY statement

EXCEPT field . . .

Indicates that the AVM displays all fields except those fields listed in the EXCEPT phrase.

WITH BROWSE browse

Indicates that the AVM displays the values into the current row of the specified browse widget.

Note: DISPLAY . . . WITH BROWSE cannot be used with a dynamic browse. Instead, the user must set the browse column’s SCREEN-VALUE attributes.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

As an exception to the general rule, the DISPLAY statement may continue to execute even if it encounters an error resolving some part of an expression. This attempt to complete the operation may result in displaying the empty string at the location of the intended output.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.
- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.
- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.
- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the
ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

Examples

This procedure generates a hierarchical report of Customers (sorted by state and name), the orders belonging to those Customers, and the order-lines belonging to each order:

```
r-disp.p
FOR EACH Customer NO-LOCK BY Customer.State BY Customer.Name:
  FOR EACH Order OF Customer NO-LOCK:
    DISPLAY Order.OrderNum Order.Name Order.ShipDate Order.PromiseDate.
    FOR EACH OrderLine OF Order NO-LOCK, Item OF OrderLine NO-LOCK:
      DISPLAY OrderLine.LineNum Item.ItemName OrderLine.Qty
      OrderLine.price.
    END.
  END.
END.
```

This procedure lists each order, Customer information, and the OrderLines for each Order. The procedure calculates an Order-value for each of the OrderLines of an Order, and adds those values to produce a total value for an entire Order.

```
r-disp2.p
FOR EACH Order NO-LOCK, Customer OF Order NO-LOCK:
  DISPLAY Order.OrderNum Customer.Name Order.ShipDate Order.PromiseDate.
  FOR EACH OrderLine OF Order NO-LOCK, Item OF OrderLine NO-UNDO:
    DISPLAY OrderLine.LineNum Item.ItemName OrderLine.Qty OrderLine.Price
    OrderLine.Qty * OrderLine.Price (TOTAL) LABEL "Order-value".
  END.
END.
```

The `r-disp3.p` procedure displays a name and address list in a mailing label. The SKIP and FORMAT options are used to produce a standard address format. The WHEN option suppresses the display of the PostalCode field if there is no postal code value in the field.
DO statement

Groups statements into a single block, optionally specifying processing services or block properties. Use an END statement to end a DO block.

Notes

• When ABL compiles a procedure, it uses a top-to-bottom pass of the procedure to design all the frames that procedure requires, adding field and related format attributes as it goes through the procedure.

• If you are displaying data that contains special control characters such as tabs, form feeds, or backspaces, be sure to use an EDITOR widget of the appropriate size for expression or base-field, or use the VIEW-AS EDITOR option from format-phrase in the DISPLAY statement. Otherwise, do not display data containing these characters.

• If you use a single qualified identifier with the DISPLAY statement, the Compiler first interprets the reference as dbname.table-name. If the Compiler cannot resolve the reference as dbname.table-name, it tries to resolve it as table-name.fieldname.

• If you invoke the DISPLAY statement for a frame, the AVM brings the frame into view unless the HIDDEN attribute for the frame or one of its ancestor frames or windows is TRUE.

• For more information on using the built-in field and buffer names, proc-text and proc-text-buffer in a DISPLAY statement, see the OpenEdge DataServer Guides (OpenEdge Data Management: DataServer for Microsoft SQL Server, OpenEdge Data Management: DataServer for ODBC, and OpenEdge Data Management: DataServer for Oracle).

• You cannot use the DISPLAY statement to display an object reference for a class instance directly. To display an object reference, you must first convert it using the INTEGER, INT64, or STRING function and display the result.

r-disp3.p

FOR EACH Customer NO-LOCK:
    Customer.PostalCode WHEN Customer.PostalCode NE "" SKIP(2)
WITH NO-BOX NO-LABELS USE-TEXT.
END.
DO statement

Syntax

```
[ label : ]
DO
    { [ FOR record [ , record ] ... ] }
    [ preselect-phrase ]
    [ query-tuning-phrase ]
    [ variable = expression1 TO expression2 [ BY k ] ]
    [ WHILE expression ]
    [ TRANSACTION ]
    [ STOP-AFTER expression ]
    [ on-endkey-phrase ]
    [ on-error-phrase ]
    [ on-quit-phrase ]
    [ on-stop-phrase ]
    { [ frame-phrase ] } :
    do-body
```

FOR record [ , record ] ...

Names the buffer you want to work with in the block and scopes the buffer to the block. The scope of a record determines when the buffer for that record is cleared and written back to the database. See OpenEdge Getting Started: ABL Essentials for more information on record scoping.

To work with a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

preselect-phrase

The PRESELECT phrase finds selected records from one or more tables. You can access those preselected records with statements such as FIND NEXT.

```
PRESELECT
    [ EACH | FIRST | LAST ] record-phrase
    [ , [ EACH | FIRST | LAST ] record-phrase ] ...
    [
        [ BREAK
            { [ BY expression [ DESCENDING ] ] } ...
        ]
    ]
```

For more information, see the PRESELECT phrase reference entry.

query-tuning-phrase

Allows programmatic control over the execution of a DataServer query.
DO statement

variable = expression1 TO expression2 [BY k]

The name of a field or variable whose value is incremented in a loop. The expression1 is the starting value for variable on the first iteration of the loop. The k is the amount to add to variable after each iteration, and it must be a constant. The k defaults to 1. The variable, expression1 and expression2 must be integers.

When variable exceeds expression2 (or is less than expression2 if k is negative) the loop ends. Since expression1 is compared to expression2 at the start of the first iteration of the block, the block can be executed zero times. The expression2 is re-evaluated on each iteration of the block.

WHILE expression

Indicates that the DO block continues processing the statements within it. Using the WHILE option turns a DO block into an iterating block. The block iterates as long as the condition specified by the expression is TRUE. The expression is any combination of constants, operators, field names, and variable names that yield a logical value.

TRANSACTION

Identifies the DO block as a system transaction block. The AVM starts a system transaction for each iteration of a transaction block if there is not already an active system transaction. See OpenEdge Getting Started: ABL Essentials for more information on transactions.

STOP-AFTER expression

The STOP-AFTER phrase specifies a time-out value for a DO, FOR, or REPEAT block. The integer expression specifies the number of seconds each iteration of a block has until a time-out occurs. If a time-out occurs, the AVM raises the STOP condition and default STOP condition handling occurs. Use an ON STOP phrase on the block (or an enclosing block) to alter the default STOP condition handling.

If the block iteration completes before the specified time expires, the timer resets to expression for the next iteration. In other words, the timer is limited to the scope of a
single block iteration. If a block with a STOP-AFTER phrase encloses another block or calls another block, the timer continues while the inner blocks execute.

If a block with a STOP-AFTER phrase contains a nested block with a STOP-AFTER phrase, then each has a timer in effect. If the outer block timer expires while the inner block is executing, the STOP condition is raised even if the timer for the inner block has not expired.

If the STOP condition is handled and execution resumes within the scope of a block with a STOP-AFTER phrase, no timer is in effect until the next iteration of a block with a STOP-AFTER phrase. In other words, all old timers are dismissed but new timers can now be established.

When the timer expires, the STOP condition is raised on the current statement.

Two important use cases for the STOP-AFTER phrase are to time-limit dynamic queries and to time-limit a procedure call. The following example time-limits a procedure call using a RUN statement:

```
DEFINE VARIABLE cnt as INTEGER INITIAL 0.
PROCEDURE bumpCnt:
  cnt = cnt + 1.
END.
DO STOP-AFTER 5:
  RUN bumpCnt.
END.
```

Use this technique to also make timed calls to class methods and user-defined functions.

The following example is simplified code that lets you try different STOP-AFTER cases.

```
DEFINE VARIABLE EndlessCount AS INTEGER INITIAL 0.
DO STOP-AFTER 5 ON STOP UNDO, LEAVE:
  FOR EACH Customer STOP-AFTER 1:
    ASSIGN EndlessCount = EndlessCount + 1.
    /* Try a complex operation on a Customer record to use up the timer in a single iteration and raise the STOP condition in the inner block */
  END.
  MESSAGE "Procedure half complete. Endlesscount = " EndlessCount ".".
  REPEAT STOP-AFTER 1:
    ASSIGN EndlessCount = EndlessCount + 1.
    /*IF EndlessCount > 2000 THEN LEAVE.*/
  END.
  MESSAGE "Procedure nearly complete. Endlesscount = " EndlessCount "."
END.
MESSAGE "Procedure complete. Endlesscount = " EndlessCount ".".
```
If you run this code as is, the outer DO block establishes a 5 second time limit for the work of the DO block and all inner blocks. When the inner FOR EACH block starts, another timer is established for the first iteration of this block. When the first FOR EACH iteration completes, its timer is reset to 1 second for the next iteration. Meanwhile, the outer timer on the DO block continues without interruption.

The FOR EACH block completes and execution continues forward to the REPEAT block, which is an endless loop. The REPEAT block also has a 1 second timer for each iteration of the block. At some point, the outer 5 second timer elapses and the AVM raises the STOP condition. The STOP condition is raised on the statement the AVM was executing when the timer elapsed. Normal STOP handling proceeds from that point.

As the stack unwinds during STOP processing, the AVM encounters the ON STOP phrase on the DO block. The ON STOP phrase dismisses the STOP condition and resumes normal execution with the next statement following the DO block, as directed by the LEAVE option.

If you remove the comments from the IF statement in the REPEAT block, the block will complete within the outer time limit and the STOP condition is not raised.

If you want to experiment with elapsed timers on an inner block, insert a complex operation inside the FOR EACH block.

In the following example, the STOP-AFTER expression is modified during program execution:

```assembly
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE stopTime AS INTEGER NO-UNDO INITIAL 30.

DO WHILE TRUE STOP-AFTER stopTime ON STOP UNDO, LEAVE:
    RUN spinHere (10000).
    stopTime = stopTime / 2.
END.
MESSAGE "program finished".

PROCEDURE spinHere:
    DEFINE INPUT PARAMETER spinLimit AS INT64 NO-UNDO.

    DEFINE VARIABLE endTime AS INT64 NO-UNDO.
    DEFINE VARIABLE loopFlag AS LOGICAL NO-UNDO.

    ASSIGN
        loopFlag = TRUE
        endTime = ETIME(FALSE) + spinLimit.

    DO WHILE loopFlag:
        IF (ETIME(FALSE) > endTime) THEN
            loopFlag = FALSE.
        END.
    END.
END PROCEDURE.
```

Because the STOP-AFTER expression is re-evaluated for each iteration of a looping block, any changes made to the expression during the iteration effect the timer for the block. In the example, the STOP-AFTER time limit is specified by the variable stopTime, which is initially set to 30 seconds. The procedure contains an iterating block which runs a procedure that executes for 10 seconds.
On the first iteration of the DO WHILE TRUE loop, stopTime is 30 seconds. The loop executes for 10 seconds, and then divides stopTime by 2. On the second iteration, the stopTime is 15 seconds; again the loop executes for 10 seconds, and then divides stopTime by 2. On the third iteration, the stopTime is 8 seconds. This time, the procedure spinHere runs for 8 seconds and then raises STOP. The STOP condition is handled by the DO block, and then the program displays the message program finished.

If a code block is called with a time limit of zero, the block is executed as if the STOP-AFTER phrase was omitted from the block declaration.

Consider the following example:

```
DEFINE VARIABLE barLimit AS INTEGER NO-UNDO.
DEFINE VARIABLE ix AS INTEGER NO-UNDO INITIAL 1.

DO STOP-AFTER 10 ON STOP UNDO, LEAVE:
  RUN foo.
END.

PROCEDURE foo:
  RUN bar.
END PROCEDURE.

PROCEDURE bar:
  DO WHILE ix > 0 STOP-AFTER barLimit:
    ix = ix + 1.
  END.
END PROCEDURE.
```

In this example, procedure foo is run from within a timed block with a 10 second time limit; procedure bar is called from within the timed block, and contains an iterating block that specifies the STOP-AFTER phrase. Because the value of the STOP-AFTER expression evaluates to zero (that is, the current value of the barLimit variable), the block within bar is executed as an untimed block. However, the rules for execution of an untimed block within a timed block apply, so the untimed block in bar is executed with an implicit iteration time limit of 10 seconds.

Other points to consider are:

- If the expression evaluates to zero or less, then this is the equivalent of not specifying a STOP-AFTER phrase.
- STOP-AFTER phrases are not intended to interact with user interfaces.
- Blocking calls to third party software components, where the AVM has transferred execution control, cannot be timed out. This category includes operating system calls, MS Windows system calls, and calls to any third party DLLs and Unix shared objects.

**on-endkey-phrase**

Describes the processing that takes place when the ENDKEY condition occurs during a block. This is the syntax for the ON ENDKEY phrase:
ON ENDKEY UNDO
[ label1 ]
[ , LEAVE [ label2 ]
| , NEXT [ label2 ]
| , RETRY [ label1 ]
| , RETURN [ return-value ]
| | ERROR [ return-value | error-object-expression ]
| | NO-APPLY ]

For more information, see the ON ENDKEY phrase reference entry.

on-error-phrase

Describes the processing that takes place when there is an error during a block. This is the syntax for ON ERROR phrase:

ON ERROR UNDO
[ label1 ]
[ , LEAVE [ label2 ]
| , NEXT [ label2 ]
| , RETRY [ label1 ]
| , RETURN [ return-value ]
| | ERROR [ return-value | error-object-expression ]
| | NO-APPLY ]
| | , THROW ]

For more information, see the ON ERROR phrase reference entry.

on-quit-phrase

Describes the processing that takes place when a QUIT statement is executed during a block. This is the syntax for ON QUIT phrase:

ON QUIT
[ UNDO [ label1 ] ]
[ , LEAVE [ label2 ]
| , NEXT [ label2 ]
| , RETRY [ label1 ]
| , RETURN [ return-value ]
| | ERROR [ return-value | error-object-expression ]
| | NO-APPLY ]

For more information, see the ON QUIT phrase reference entry.
on-stop-phrase

Describes the processing that takes place when the STOP conditions occurs during a block. This is the syntax for the ON STOP phrase:

```
ON STOP UNDO
  [ label1 ]
  [ , LEAVE [ label2 ]
   | , NEXT [ label2 ]
   | , RETRY [ label1 ]
   | , RETURN [ return-value ]
   ERROR [ return-value | error-object-expression ]
   NO-APPLY ]
```

For more information, see the ON STOP phrase reference entry.

frame-phrase

Specifies the overall layout and processing properties of a frame. For more information on frame-phrase, see the Frame phrase reference entry.

do-body

The body of the DO block. Define do-body using the following syntax:

```
do-logic
  .
  .
  [ catch-block [ catch-block ... ] ]
  [ finally-block ]
END .
do-logic
```

do-logic

The logic of the DO block. This logic can contain the ABL statements allowed within the routine-level block (e.g., procedure, user-defined, or method) where the DO statement is defined.

Each logic statement must end with a period.

catch-block

Specifies a CATCH statement that defines error handling code for one or more error types. Since a DO block does not have any default error handling, a CATCH block is only valid within it if the block specifies error handling options. At this point, the block can raise ERROR and a CATCH block is valid to handle errors. If a DO block does not have error handling options and specifies a CATCH block, ABL generates a compiler warning. For more information on catch-block, see the CATCH statement reference entry.
**finally-block**

Specifies a FINALLY statement that defines the processing that must occur after all other processing in the block occurs. For more information on finally-block, see the FINALLY statement reference entry.

**END**

Specifies the end of the DO block definition. You must end the DO block definition with the END statement.

**Example**

This procedure goes through the Customer table and, for those Customers whose CreditLimit is over 80000, reduces CreditLimit to 80000. The procedure uses an unmodified DO block to process two statements if CreditLimit is over 80000. Unmodified DO blocks are most useful in conditional, or IF...THEN...ELSE situations.

```plaintext
r-do.p

FOR EACH Customer NO-LOCK:
   DISPLAY Customer.Name Customer.CreditLimit.
   PAUSE 3.
   IF Customer.CreditLimit > 80000 THEN DO:
      Customer.CreditLimit = 80000.
      DISPLAY Customer.Name Customer.CreditLimit.
   END.
END.
```

**Notes**

- Use a DO statement rather than a REPEAT statement when you loop through each element of an array. This way the AVM does not create separate subtransactions within a transaction.

  For example, the first transaction is more efficient then the second:

  ```plaintext
  DO ix = 1 TO 12:
      SalesRep.MonthQuota[ix] = 0.
  END.
  ```

  ```plaintext
  REPEAT ix = 1 TO 12:
      SalesRep.MonthQuota[ix] = 0.
  END.
  ```

- For SpeedScript, the on-endkey-phrase and the on-quit-phrase do not apply.

**See also**

CATCH statement, FINALLY statement, FIND statement, FOR statement, Frame phrase, ON ENDKEY phrase, ON ERROR phrase, ON QUIT phrase, ON STOP phrase, Record phrase, REPEAT statement
DOS statement

(Windows only)

Runs a program, DOS command, or DOS batch file, or starts the DOS command processor, which allows interactive processing of DOS commands.

Syntax

```
DOS [ SILENT ] [ command-token | VALUE ( expression ) ] ...
```

SILENT

After processing a DOS statement, the AVM shell pauses, and prompts you to press `SPACEBAR` to continue. When you press `SPACEBAR`, the AVM clears the window and continues processing. You can use the SILENT option to eliminate this pause. Use this option only if you are sure that the DOS program, command, or batch file will not generate output to the window.

```
command-token | VALUE ( expression )
```

One or more command (`command-token`) words and symbols that you want to pass to a DOS command processor. The VALUE option generates the command tokens included in `expression`, a character string expression. The specified combination of `command-token` and VALUE (`expression`) options can form any legal combination of commands and command options permitted by the DOS command processor, including programs, DOS commands, and batch files. If you do not use any of these options, the DOS statement invokes the DOS command processor, which remains until you exit it.

Example

On UNIX, this procedure runs the UNIX `ls` command. In Windows, this procedure runs the DOS `dir` command. On other platforms, the AVM displays a message stating that the operating system is unsupported.

```
r-dos.p
```

```
IF OPSYS = "UNIX" THEN UNIX ls.
ELSE IF OPSYS = "WIN32" THEN DOS dir.
ELSE DISPLAY OPSYS "is an unsupported operating system".
```

Note

If you use the DOS statement in a procedure and the procedure compiles on a UNIX system, the procedure runs, as long as flow of control does not pass through the DOS statement while running on UNIX. Use the OPSYS function to return the name of the operating system where a procedure is being run. This function lets you write applications that are portable among OpenEdge-supported operating systems even if they use the DOS, UNIX, etc. statements.

See also

{ } Preprocessor name reference, OPSYS function, UNIX statement

DOWN statement

Positions the cursor on a new line in a down or multi-line frame.
When the block specifying the down frame iterates, the AVM automatically advances one frame line. Use the DOWN statement if you want to move to a different display line at any time.

For more information on down frames, see the DOWN option of the Frame phrase.

**Note:** Does not apply to SpeedScript programming.

### Syntax

```
DOWN [ STREAM stream ] [ STREAM-HANDLE handle ] [ expression ]
{ [ frame-phrase ] }
```

**STREAM stream**

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream. See the DEFINE STREAM statement reference entry and the "Alternate I/O Sources" chapter in *OpenEdge Development: Programming Interfaces* for more information on streams.

**STREAM-HANDLE handle**

Specifies the handle to a stream. If handle is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in *OpenEdge Development: Programming Interfaces* for more information on streams and stream handles.

**expression**

The number of occurrences of data in the frame that you want to move down.

DOWN is the same as DOWN 1, except for the following:

- Nothing happens until a data handling statement affects the screen.
- Several DOWN statements in a row with no intervening displays are treated as a single DOWN 1.

DOWN 0 does nothing. If \( n \) is negative, the result is the same as UP ABS(\( n \)).

**frame-phrase**

Specifies the overall layout and processing properties of a frame. For more information on **frame-phrase**, see the Frame phrase reference entry.

### Example

This procedure prints a Customer report that is sorted by State, with one line after the last Customer in each state:
DYNAMIC-CAST function

Returns a new object reference to the same class instance as an existing object reference, but with a different data type. This different data type is cast from the object type of the original object reference according to another object type specified by a run-time expression. The object types must be related, where one is a class type and the other is subclass of that class type or where one is an interface type and the other is a class that implements the interface of that type.

When you cast an object reference, ABL treats it as if it referenced an instance of the object type to which it is cast. The underlying class hierarchy of the object instance does not change.

Syntax

DYNAMIC-CAST( object-reference, expression ).

object-reference

An object reference defined with the object type to be cast.

expression

A character expression that evaluates to the fully qualified type name for the ABL or .NET class or interface type to which the object reference is cast. This object type must be a class type in a class hierarchy that includes or implements the object-reference data type or it must be an interface type that the object-reference data type implements. However, the object type cannot be a .NET generic type. Specify an object type name using the syntax described in the Type-name syntax reference entry. Any present USING statement

Notes

- After displaying a down frame, the AVM automatically advances to the next frame line on each iteration of the block where the frame belongs. This is true whether or not you use the DOWN statement. If you do not want the AVM to advance automatically, name the frame outside of the block involved (the statement FORM WITH FRAME frame names a frame and scopes that frame to the higher block).

- When the AVM reaches the last frame line and encounters a DOWN statement, it clears the frame and starts at the top line of the frame, unless you used the SCROLL option on the frame. In that case, the AVM scrolls the frame up one iteration only, to make room for the next iteration.

See also

DEFINE STREAM statement, Frame phrase, SCROLL statement, Stream object handle, UP statement

DYNAMIC-CAST function

r-down.p

```abl
DEFINE VARIABLE laststate AS CHARACTER NO-UNDO.
FOR EACH Customer NO-LOCK BY Customer.State:
  IF Customer.State <> laststate THEN DO:
    IF laststate <> "" THEN DOWN 1.
    laststate = Customer.State.
  END.
END.
```

```
has no effect. If no package is specified, the class or interface name must represent the complete type name.

Notes

- You typically cast an object reference down a class hierarchy—that is, from a super class to a derived class within a class hierarchy, or from an interface to a class that implements that interface. However, you do not always need to explicitly cast an object reference. Because a derived class contains all the super classes in its inherited class hierarchy, ABL implicitly casts any object reference up within its class hierarchy, and because a class that implements an interface implements all of the methods specified for the interface, ABL implicitly casts any object reference from an implementing class to any interface that the class implements.

- At run time, ABL verifies that the object type specified by expression is within the class hierarchy of the specified object reference. Therefore, if you access a class member on the cast object reference that exists for the cast data type, but the referenced object does not actually define the accessed class member, the AVM raises a run-time ERROR.

- A .NET generic type can be part of a cast. For example, you can cast from a System.Object to a "System.Collections.Generic.List<SHORT>", because all .NET classes, including generic classes, derive from the .NET root class. However, note that you cannot cast from a "System.Collections.Generic.List<System.Object>" to a "System.Collections.Generic.List<System.Windows.Forms.Button>". You cannot assign a "List<Button>" reference to an object reference defined as a "List<Object>", because, even though the type parameters are compatible, the two objects as a whole are not equivalent and have no inheritance relationship. Therefore, a cast between these two objects cannot work either. For more information on .NET generic types, see the Data types reference entry.

- You can also use the CAST function to perform all casting operations at compile time. The primary reason for using the DYNAMIC-CAST function is to cast object references based on run-time conditions that determine the object type to use for the cast. Such conditions are common in applications that conform to the OpenEdge Reference Architecture (OERA). For more information on the OERA, see the Progress Software Developers Network (PSDN): http://communities.progress.com/pcom/community/psdn.

- You can use the DYNAMIC-CAST function to cast a parameter in a parameter list for a method using the following syntax, where expression evaluates to a subclass of the object-reference type:

```plaintext
method-name( INPUT DYNAMIC-CAST( object-reference, expression ), ... ).
```

- You can use the DYNAMIC-CAST function to cast a temp-table field, which is defined as a Progress.Lang.Object, to use as an object of another class type. For example:

```plaintext
DEFINE VARIABLE RCustObj AS CLASS acme.myObjs.CustObj.
DEFINE TEMP-TABLE mytt NO-UNDO
RCustObj = DYNAMIC-CAST(mytt.CustObj, "acme.myObjs.CustObj").
```
You can now use the object reference in `RCustObj` to invoke methods in the `acme.myObjs.CustObj` class.

- You **cannot** use the DYNAMIC-CAST function to cast an object reference to a subclass and invoke a method defined in that subclass using the following syntax:

```
```

Similarly, you cannot use this syntax to invoke a method on a class that implements the referenced interface from which you cast the specified class.

See also  
CAST function, Type-name syntax, USING statement

---

**DYNAMIC-CURRENT-VALUE function**

Returns the current INT64 value of a sequence defined in the specified database.

**Syntax**

```
DYNAMIC-CURRENT-VALUE( sequence-expression, logical-dbname-expression )
```

*sequence-expression*

A character expression that evaluates to the name of a sequence.

*logical-dbname-expression*

A character expression that evaluates to the name of a connected database in which the sequence is defined.

**Notes**

- If `logical-dbname-expression` contains the Unknown value (`?`), the AVM generates a run-time error.
- The user must have CAN-READ privileges on the _Sequence table to use the DYNAMIC-CURRENT-VALUE function.
- The current value of a sequence can be one of the following:
  - The initial value specified in the Data Dictionary.
  - The last value set with either the DYNAMIC-CURRENT-VALUE statement or the DYNAMIC-NEXT-VALUE function.
  - The Unknown value (`?`) if the sequence has exceeded its minimum or maximum and is not cycling.
- Sequence values are stored in the database in which they are defined, and persist between each invocation of the DYNAMIC-CURRENT-VALUE statement or DYNAMIC-NEXT-VALUE function.
- You cannot invoke the DYNAMIC-CURRENT-VALUE function from within a WHERE clause. Doing so generates a compiler error. To use a result from the
DYNAMIC-CURRENT-VALUE function in a WHERE clause, assign the result to a variable, then use the variable in the WHERE clause.

- You can use any combination of the DYNAMIC-NEXT-VALUE function, DYNAMIC-CURRENT-VALUE function, DYNAMIC-CURRENT-VALUE statement, and their non-dynamic versions.

See also CURRENT-VALUE function, CURRENT-VALUE statement, DYNAMIC-CURRENT-VALUE statement, DYNAMIC-NEXT-VALUE function, NEXT-VALUE function

DYNAMIC-CURRENT-VALUE statement

Resets the current integer value of a sequence defined in the specified database.

**Syntax**

```
DYNAMIC-CURRENT-VALUE( sequence-exp, logical-dbname-exp ) = expression
```

**sequence-exp**

A character expression that evaluates to the name of a sequence.

**logical-dbname-exp**

A character expression that evaluates to the name of a connected database in which the sequence is defined.

**expression**

An integer expression assigned as the current value of the specified sequence. If `expression` is outside the boundary set by the initial value (at one end) and the lower limit or upper limit (at the other end) for the sequence, the AVM returns an error, and the sequence value remains unchanged.

**Notes**

- If `logical-dbname-exp` contains the Unknown value (?), the AVM generates a run-time error.
- You cannot set a sequence to the Unknown value (?).
- The user must have CAN-WRITE privileges on the _Sequence table to use the DYNAMIC-CURRENT-VALUE statement.
- The value of a sequence set by the DYNAMIC-CURRENT-VALUE statement persists in the database until the next DYNAMIC-CURRENT-VALUE statement or DYNAMIC-NEXT-VALUE function is invoked for the sequence, or until the sequence is deleted from the database.
- You can use any combination of the DYNAMIC-NEXT-VALUE function, DYNAMIC-CURRENT-VALUE function, DYNAMIC-CURRENT-VALUE statement, and their non-dynamic versions.

See also CURRENT-VALUE function, CURRENT-VALUE statement, DYNAMIC-CURRENT-VALUE function, DYNAMIC-NEXT-VALUE function, NEXT-VALUE function
DYNAMIC-FUNCTION function

Invokes a user-defined function. The AVM evaluates the name of the function (and the procedure handle, if any) at run time.

Syntax

DYNAMIC-FUNCTION

( function-name [ IN proc-handle ]
  [ , param1 [ , param2 ] . . . ]
)

function-name

A CHARACTER expression that returns the name of a user-defined function. The AVM evaluates function-name at run time.

IN proc-handle

An expression that returns a handle to the procedure that defines the function. The AVM evaluates proc-handle at run time.

param1, param2, ...

Parameters of the user-defined function. You must supply names of actual data items—actual parameter names—not CHARACTER expressions that return parameter names.

Note: ABL cannot check the mode and type of the parameters at compile time, since the AVM does not evaluate function-name until run time.

Example

The following procedure demonstrates the DYNAMIC-FUNCTION function:
r-funfun.p

/* Requires a connection to the Sports2000 database. Define data items */
DEFINE VARIABLE funcs AS CHARACTER NO-UNDO EXTENT 5
   INITIAL ['firstrec','lastrec','nextrec','prevrec','quitting'].
DEFINE VARIABLE action AS CHARACTER NO-UNDO LABEL "Action" FORMAT "x"
   INITIAL "N".
DEFINE VARIABLE idx AS INTEGER NO-UNDO.
DEFINE VARIABLE alldone AS LOGICAL NO-UNDO.

FORM WITH FRAME x SIDE-LABELS 2 COLUMNS 1 DOWN COLUMN 25.

/* Define user-defined functions */
FUNCTION dispcust RETURNS LOGICAL:
   DISPLAY Customer EXCEPT Customer.Comments WITH FRAME x.
END.

FUNCTION firstrec RETURNS LOGICAL:
   FIND FIRST Customer.
   dispcust().
   RETURN yes.
END.

FUNCTION lastrec RETURNS LOGICAL:
   FIND LAST Customer.
   dispcust().
   RETURN yes.
END.

FUNCTION nextrec RETURNS LOGICAL:
   FIND NEXT Customer NO-ERROR.
   IF AVAILABLE Customer THEN
      dispcust().
   RETURN AVAILABLE(Customer).
END.

FUNCTION prevrec RETURNS LOGICAL:
   FIND PREV Customer NO-ERROR.
   IF AVAILABLE Customer THEN
      dispcust().
   RETURN AVAILABLE(Customer).
END.

FUNCTION quitting RETURNS LOGICAL:
   alldone = yes.
   RETURN no.
END

/* Main routine */
REPEAT WHILE NOT alldone:
   UPDATE action HELP
      "Enter F(irst), L(ast), N(ext), P(rior), or Q(uit) to navigate.".
   idx = LOOKUP(action,"f,l,n,p,q").
   IF idx EQ 0 THEN DO:
      MESSAGE "Enter F(irst), L(ast), N(ext), P(rior), or Q(uit)"
      VIEW-AS ALERT-BOX.
      NEXT.
   END.
   DISPLAY DYNAMIC-FUNCTION(funcs[idx]) LABEL "Record Found?".
END.

See also FUNCTION statement
DYNAMIC-INVOKE function

Invokes a class-based method whose name is specified by a run-time expression, but whose parameters are defined at compile time.

Syntax

```
[ return-value = ] DYNAMIC-INVOKE( { class-type-name | object-reference },
method-name [ , parameter [ , parameter ] ... ] )
```

**return-value**

An optional data element that is assigned the return value from the invoked, non-void method. This data element can be any data type. The AVM checks `return-value` at run time for data type compatibility with what is actually returned by the method.

ABL raises a run-time error if you invoke a void method where a return value is expected.

**class-type-name**

The name of an ABL or .NET class type that defines the specified method as a static member. If the method is static, this parameter is a CHARACTER expression that the AVM evaluates to the type name of the class at run time. This expression must specify a class type name as described in the 'Type-name syntax' reference entry, except that you must always specify the complete type name; any present USING statement has no effect. You cannot use `class-type-name` to call an instance method. For more information on specifying class type names, see the 'Type-name syntax' reference entry.

**object-reference**

Specifies a reference to an ABL or .NET class instance that defines the specified method as an instance member. You cannot use `object-reference` to call a static method. For information on specifying object references, see the reference entry for a Class-based object reference.

**method-name**

A CHARACTER expression that evaluates to the method name. The AVM evaluates `method-name` at run time.

```
[ , parameter [ , parameter ] ... ]
```

Specifies zero or more parameters passed to the method. You must provide the parameters identified by the specified method, matched with respect to number, data type, and mode. To invoke a method that is overloaded in the class, you must specify sufficient information for each `parameter` in order to disambiguate methods that have similar parameter lists. Otherwise, the AVM raises an error identifying the ambiguity.

If the parameter mode (INPUT, OUTPUT, INPUT-OUTPUT) is not specified, the mode defaults to INPUT. This differs from normal invocation of a method, where the parameter mode defaults to the method parameter. In this case, the compiler does not know the method at compile time, and therefore must use INPUT for the default, instead of inferring it from the called method. We recommended that you always supply the parameter mode.
For more information on parameter passing syntax and on disambiguating overloaded ABL and .NET methods, see the Parameter passing syntax reference entry.

**Note:** The Invoke( ) method of the Progress.Lang.Class class provides similar functionality to the DYNAMIC-INVOKE function. The advantage to the latter is that it has a fixed, compile-time parameter list and does not require the creation of a ParameterList object at run time.

**See also:** DYNAMIC-NEW statement, Invoke( ) method (Class), New( ) method, Parameter passing syntax, Progress.Lang.Class class

### DYNAMIC-NEW statement

Creates an instance of a class (object) whose class type is specified by a run-time expression, and assigns its object reference to an appropriately defined ABL data element. Once assigned, you can use the object reference to access this class instance and its PUBLIC data members, properties, and methods. For more information on object references, see the reference entry for a Class-based object reference.

**Syntax**

```
object-reference = DYNAMIC-NEW expression
( [ parameter [ , parameter ] ... ] ) [ NO-ERROR ]
```

**object-reference**

The name of an ABL data element to which you want to assign the object reference of a new instance of the class specified by `expression`. This data element must be defined as a compatible class or interface type, and can be one of the following:

- A temp-table field defined as a Progress.Lang.Object class type using the DEFINE TEMP-TABLE statement
- A variable scoped to the current procedure, user-defined function, or method of a class, or an accessible class-based variable data member, each defined as a class or interface type using the DEFINE VARIABLE statement
- A parameter defined as a class or interface type for the current procedure, user-defined function, or method of a class using an appropriate DEFINE PARAMETER statement or Parameter definition syntax
- An accessible and writable class-based property defined as a class or interface type using the DEFINE PROPERTY statement

To be compatible, the data type of `object-reference` must be:

- The same class as the class specified by `expression`
- A super class of the class specified by `expression`
- An interface that is implemented by the class specified by `expression`
expression

A character expression that evaluates to a fully qualified class type name for the ABL or .NET class you want to instantiate. This expression must specify a class type name as described in the Type-name syntax reference entry, except that you must always specify the complete type name; any present USING statement has no effect. If no package (or namespace for a .NET class) is specified, the class name must represent the complete type name.

This expression cannot evaluate to:

- An ABL built-in class type name, such as Progress.Lang.Object
- The type name of an interface or abstract class

\( [ \text{parameter} [ , \text{parameter} ] \ldots ] \)

Specifies zero or more parameters passed to a PUBLIC instance constructor that is defined for the class. You must provide the parameters identified by the specified constructor, matched with respect to number, data type, and mode.

For information on the parameter passing syntax, see the Parameter passing syntax reference entry.

For information on defining a constructor for a class, see the CONSTRUCTOR statement reference entry.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

For the DYNAMIC-NEW statement with NO-ERROR, if ERROR is raised, then the object-reference remains unchanged. If a RETURN statement or an UNDO statement with the THROW or RETURN ERROR options in a constructor raises ERROR and also returns an error string, you can obtain this string value after the assignment statement completes using the RETURN-VALUE function.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.
- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object.
generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE(message-num) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.
- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.
- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.
- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

Example

The following contrived (non-compiling) procedure fragment shows the instantiation of a new class type specified with a variable:

```hll
/* Can be set to a subclass type name */
DEFINE INPUT PARAMETER myBusObjParm AS CHARACTER NO-UNDO.

/* Procedure only knows about the base class */
DEFINE VARIABLE myBusObj AS CLASS acme.myObjs.BusObj NO-UNDO.

myBusObj = DYNAMIC-NEW myBusObjParm ( ). /* Create the passed subclass */
myBusObj:getData( ). /* Invoke base class method polymorphically on subclass */
```

In this case, the procedure assumes that it is operating on a class, acme.myObjs.BusObj, that is the base class for several subclasses, each of which implements the same set of operations for its own purposes, such as the getData() method shown. When the procedure is called, its INPUT parameter is passed a character string that evaluates to a subclass type name, such as "acme.myObjs.CustObj", which it then uses to instantiate a class of that type using the DYNAMIC-NEW statement. Thus, the same procedure can be called to instantiate and operate on different subclasses of the same base class, as determined by run-time conditions.
Notes

• Unlike NEW, you cannot use DYNAMIC-NEW as a function in an expression. You can use it only in the context of this statement.

• When executed in the context of the DYNAMIC-NEW statement, the specified class constructor can execute input-blocking statements (such as the WAIT-FOR statement (ABL only)). This is different from a NEW function (classes) executed in the context of an expression, which cannot invoke a constructor that executes input-blocking statements.

• After the assignment, object-reference contains a copy of the object reference value returned by DYNAMIC-NEW, which points to the same object instance, not a copy of the object created by DYNAMIC-NEW.

• Although you can assign an object reference to a temp-table field defined as a Progress.Lang.Object class type, you cannot assign an object reference to a field in a database table. For more information, see OpenEdge Development: Object-oriented Programming.

• The ABL Virtual Machine (AVM) automatically deletes (garbage collects) any class instance that you create with this statement some time after no reference to that object exists in the ABL session. However, you can force any class instance to be deleted immediately by using the DELETE OBJECT statement. For more information on garbage collection for class instances, see the DELETE OBJECT statement reference entry.

• If expression specifies a .NET object, note that in ABL you cannot instantiate the following .NET classes:
  – Any .NET class that is defined in the default namespace, that is, where the class name is the complete object type name
  – System.Threading.Thread or any class derived from it
  – System.Delegate or any delegate type derived from it

• This statement can raise errors during the execution of constructors for the class being instantiated, or for any class in its inherited class hierarchy. For example:
  – A constructor in the class hierarchy executes the RETURN statement with the ERROR option or the UNDO statement with the THROW or RETURN ERROR options.
  – The class definition file for the class, a super class, or an interface could not be found.
  – The run-time parameters of the constructor for the class, or a constructor for a class in the inherited class hierarchy, are not compatible.

When the AVM encounters one of these errors, and the constructor cannot create the class instance or its inherited class hierarchy, the AVM automatically invokes the destructor for any class that has already been constructed while building the class hierarchy for the object.

For more information on errors raised by instantiating classes, see OpenEdge Development: Object-oriented Programming.

• The New( ) method of the Progress.Lang.Class class provides similar functionality to the DYNAMIC-NEW function. The advantage to the latter is that it has a fixed, compile-time
DYNAMIC-NEXT-VALUE function

parameter list and does not require the creation of a Progress.Lang.ParameterList object at run time.

See also
Assignment (=) statement, Class-based object reference, CLASS statement, DYNAMIC-CAST function, DYNAMIC-INVOKE function, Invoke() method (Class), NEW function (classes), New() method, NEW statement, Parameter passing syntax, Progress.Lang.ParameterList class

DYNAMIC-NEXT-VALUE function

Returns the next INT64 value of a sequence, incremented by the positive or negative value defined in the specified database.

Syntax

```
DYNAMIC-NEXT-VALUE( sequence-expression, logical-dbname-expression )
```

sequence-expression

A character expression that evaluates to the name of a sequence.

logical-dbname-expression

A character expression that evaluates to the name of a connected database in which the sequence is defined.

Notes

• If logical-dbname-expression contains the Unknown value (?), the AVM generates a run-time error.

• If sequence-expression is a cycling sequence, and the DYNAMIC-NEXT-VALUE function increments the sequence beyond its upper limit (for positive increments) or decrements the sequence beyond its lower limit (for negative increments), the function sets and returns the initial value defined for the sequence.

• If sequence-expression is a terminating sequence, and the DYNAMIC-NEXT-VALUE function attempts to increment the sequence beyond its upper limit (for positive increments) or decrement the sequence beyond its lower limit (for negative increments), the function returns the Unknown value (?) and leaves the current sequence value unchanged. Once a sequence terminates, DYNAMIC-NEXT-VALUE continues to return the Unknown value (?) for the specified sequence until it is reset to a new value with the DYNAMIC-CURRENT-VALUE statement, or its definition is changed to a cycling sequence. After changing the sequence definition to cycle, the first use of DYNAMIC-NEXT-VALUE for the sequence sets and returns its initial value.

• The value of a sequence set by the DYNAMIC-NEXT-VALUE function persists in the database until the next DYNAMIC-CURRENT-VALUE statement or DYNAMIC-NEXT-VALUE function is invoked for the sequence, or until the sequence is deleted from the database.

• You cannot invoke the DYNAMIC-NEXT-VALUE function from within a WHERE clause. Doing so generates a compiler error because the value returned by the DYNAMIC-NEXT-VALUE function can result in ambiguous expressions. To use a result from the DYNAMIC-NEXT-VALUE function in a WHERE clause, assign the result to a variable and use the variable in the WHERE clause instead.
You can use any combination of the DYNAMIC-NEXT-VALUE function, DYNAMIC-CURRENT-VALUE function, DYNAMIC-CURRENT-VALUE statement, and their non-dynamic versions.

See also

CURRENT-VALUE function, CURRENT-VALUE statement, DYNAMIC-CURRENT-VALUE function, DYNAMIC-CURRENT-VALUE statement, NEXT-VALUE function
**EDITING phrase**

Identifies the process that follows each keystroke during a PROMPT-FOR, SET, or UPDATE statement.

This phrase is maintained primarily for compatibility with Progress Version 6 or earlier.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
[ label?: ] EDITING: statement ... END
```

*statement*

One or more statements you want to process, usually for each keystroke entered. In most cases, the first statement is READKEY.

**Example**

This procedure lets you update the `ix` variable, and immediately processes each of your keystrokes. The READKEY statement reads each of the keys you press. The APPLY statement applies, or executes, each keystroke. This is a very simple EDITING phrase and is the same as entering UPDATE `ix`.

**r-edit.p**

```
DEFINE VARIABLE ix AS INTEGER NO-UNDO.

UPDATE ix EDITING:
   READKEY.
   APPLY LASTKEY.
END.
```

The following r-edit2.p procedure uses an EDITING phrase with an UPDATE statement to control what happens based on each keystroke during the UPDATE. Here, the user can press any key while updating any field except SalesRep.

While in the SalesRep field, the user can press SPACEBAR to scroll through the possible values for the SalesRep field. If the user presses the TAB, BACKTAB, GO, RETURN, or END-ERROR key, the procedure executes that key. If the user presses any other key while in the SalesRep field, the terminal beeps.
Notes

• A READKEY statement does not have to be the first statement after the word EDITING. However, it should appear somewhere in the EDITING phrase because the AVM does not automatically read keystrokes when you use an EDITING phrase.

• The EDITING phrase applies to the PROMPT-FOR part of a SET or UPDATE statement. Therefore, to examine a value supplied by the user (within an EDITING phrase), you must use the INPUT function to refer to the field or variable that contains the value.

• When you use the NEXT statement in an EDITING phrase, the AVM executes the next iteration of that EDITING phrase and cancels any pending GO.

• When you use the LEAVE statement in an EDITING phrase, the AVM leaves the EDITING phrase and executes the assignment part of the SET or UPDATE statement.

• Within an EDITING phrase, you cannot use the CLEAR ALL, DOWN, or UP statements on the frame being edited.

• If you hide and redisplay a frame while you are in an EDITING block, the AVM might not redisplay it in the same location unless you specifically name the row and column of the frame. This could cause problems because the EDITING block does not recognize the new location, and attempts to update the fields at the old frame location.

• The EDITING phrase activates only for input from a terminal. If your input comes from an operating system file (set with the INPUT FROM statement), the EDITING phrase has no effect.
• The EDITING phrase is incompatible with event-driven programming. An EDITING block might interfere with other event handling statements.

• For more information on EDITING blocks and other ways of monitoring keystrokes, see *OpenEdge Development: Programming Interfaces*.

**See also** END statement, PROMPT-FOR statement, READKEY statement, SET statement, UPDATE statement

## EDITOR phrase

Specifies that a field or variable is displayed as a text editor widget. This is especially useful for long text (CHARACTER and LONGCHAR) fields. The EDITOR phrase is an option of the VIEW-AS phrase.

### Syntax

```
EDITOR
  { size-phrase
    | INNER-CHARS chars INNER-LINES lines
  }
  [ BUFFER-CHARS chars ]
  [ BUFFER-LINES lines ]
  [ LARGE ]
  [ MAX-CHARS characters ]
  [ NO-BOX ]
  [ NO-WORD-WRAP ]
  [ SCROLLBAR-HORIZONTAL ]
  [ SCROLLBAR-VERTICAL ]
  [ TOOLTIP tooltip ]
```

**size-phrase**

Specifies the outer width and height of the text editor widget in characters or pixels. This is the syntax for size-phrase:

### Syntax

```
{ SIZE | SIZE-CHARS | SIZE-PIXELS } width BY height
```

For more information, see the SIZE phrase reference entry.

**INNER-CHARS chars INNER-LINES lines**

Specifies the number of characters visible in each line of the Editor and the number of lines visible within the Editor. Both *chars* and *lines* must be integer constants.

Note that the values you supply for INNER-CHARS and INNER-LINES specify only the size of the editing area, not the overall size of the editor widget. The overall size is determined by the size of the editing area plus the sizes of the margin and border heights and widths.
BUFFER-CHARS  chars

In character mode, specifies the number of characters a user can enter on each line. When
the last character is typed, the text input cursor automatically wraps to the next line. This
option is ignored in graphical environments.

The chars value must be an integer constant that is equal to or greater than the value
specified by SIZE width or INNER-CHARS chars. If greater, horizontal scrolling is
enabled. The default is the value specified by SIZE width or INNER-CHARS chars.

BUFFER-LINES  lines

In character mode, specifies the number of lines a user can enter. By default, ABL does
not limit the number of lines (although system limits might apply). This option is ignored
in graphical environments.

The lines value must be an integer constant that is equal to or greater than the value
specified by BY height or INNER-LINES lines. If equal, vertical scrolling is disabled.

LARGE

Specifies that ABL use a large editor widget rather than a normal editor widget in
Windows. A normal Windows editor can contain up to 20K of data. The LARGE option
allows the editor to contain data up to the limit of your system resources. However, it also
consumes more internal resources and lacks some functionality. Use the LARGE option
only if you have to edit very large sections of text. The LARGE option applies only to
Windows; other interfaces allow for larger editors by default. This option is ignored in
those other interfaces.

MAX-CHARS  characters

The maximum number of characters that can be displayed or entered within the text editor
widget. The value characters must be an integer constant. By default, ABL does not limit
the number of characters (although system limits might apply).

NO-BOX

Specifies that the editor be displayed without a border. The default is to display the editor
with a border. The NO-BOX option has no effect on the size of the editor.

NO-WORD-WRAP

Specifies that word wrap be disabled within the text editor widget. If you enable word
wrap, horizontal scrolling is disabled. This option is ignored in character mode. This is the
default with the LARGE option.

SCROLLBAR-HORIZONTAL

Specifies that horizontal scrolling is enabled and a horizontal scroll bar is displayed for the
widget.

SCROLLBAR-VERTICAL

Specifies that a vertical scroll bar is display for the widget. Although vertical scrolling is
always enabled within a text editor widget, a vertical scroll bar is displayed only if you
specify this option.
TOOLTIP tooltip

Allows you to define a help text message for a text field or text variable. The AVM automatically displays this text when the user pauses the mouse button over a text field or text variable for which a tooltip is defined.

You can add or change the TOOLTIP option at any time. If TOOLTIP is set to "" or the Unknown value (?), then the tooltip is removed. No tooltip is the default. The TOOLTIP option is supported in Windows only.

Example

The following example uses two editor widgets. The Item.CatDescription field is viewed as an EDITOR in the item-info frame and the variable my_clipbd is viewed as an EDITOR in the clip frame. Use the EDITOR functions provided by your interface environment to copy text from CatDescription into my_clipbd. You can then subsequently copy that text into the CatDescription field of another item.

r-vaedit.p

```forth
DEFINE VARIABLE my_clipbd AS CHARACTER NO-UNDO
   VIEW-AS EDITOR SIZE 60 BY 6 SCROLLBAR-VERTICAL LABEL "Scratch Pad".

DEFINE BUTTON b_quit LABEL "Quit" AUTO-ENDKEY.

FORM
   Item.ItemNum
   Item.ItemName
   Item.Price
   Item.OnHand
   Item.Allocated
   Item.ReOrder
   Item.OnOrder
   Item.CatPage
   Item.CatDescription VIEW-AS EDITOR SIZE 35 BY 3 SCROLLBAR-VERTICAL
   WITH FRAME item-info 1 DOWN ROW 1 CENTERED SIDE-LABELS
       TITLE "Update Item Category Description".

FORM my_clipbd WITH FRAME clip.

DEFINE FRAME butt-frame b_quit
   WITH CENTERED ROW 18.

ON GO OF Item.ItemNum DO:
   FIND Item USING Item.ItemNum EXCLUSIVE-LOCK.
   DISPLAY Item WITH FRAME item-info.
   ENABLE Item.CatDescription WITH FRAME item-info.
   ENABLE my_clipbd WITH FRAME clip.
END.

ON GO OF Item.CatDescription DO:
   ASSIGN Item.CatDescription.
   CLEAR FRAME item-info.
   DISABLE Item.CatDescription WITH FRAME item-info.
END.

ENABLE Item.ItemNum WITH FRAME item-info.
ENABLE b_quit WITH FRAME butt-frame.

WAIT-FOR WINDOW-CLOSE OF CURRENT-WINDOW.
```

Notes

- If you specify the SCROLLBAR-VERTICAL option in, a vertical scroll bar appears on the side of the Editor. The user can then use the scroll bar to scroll within the widget.
Whether or not you specify SCROLLBAR-VERITCAL, the user can scroll vertically by using the up and down arrow keys to move above or below the displayed text.

- If you use the SIZE phrase to specify the dimensions of the Editor, the AVM uses a portion of this overall space (thereby shrinking the size of the editing area) for any scroll bars you specify. Use the INNER-CHARS and INNER-LINES options if you want a fixed size for the editing area, regardless of the presence of scroll bars.

- In Windows, the editor widget supports lines of up to 255 characters only.

- By default, the editor widget supports text wrap. This means that when you reach the end of a line within the widget, text wraps to the next line rather than scrolling to the right. In graphical interfaces, you can enable horizontal scrolling by specifying either the NO-WORD-WRAP or SCROLLBAR-HORIZONTAL options. If you specify SCROLLBAR-HORIZONTAL, a horizontal scroll bar appears. If you specify NO-WORD-WRAP, but not SCROLLBAR-HORIZONTAL, the user can scroll horizontally by using the left and right arrow keys at the edge of the displayed text.

- Windows allows a user to transfer focus to the editor by pressing \textit{ALT} and one of the letters in the label. This is called a \textit{mnemonic}.

- The character-mode editor does not support the tab character. When the AVM reads a file that contains tabs into an editor widget, it replaces the tabs with eight spaces. When it writes the file, the tabs are not restored and the file is permanently changed.

- When you specify the LARGE option, the following attributes and methods no longer apply to the editor:
  - CONVERT-TO-OFFSET method
  - CURSOR-OFFSET attribute
  - LENGTH attribute
  - MAX-CHARS attribute
  - SELECTION-END attribute
  - SELECTION-START attribute
  - SET-SELECTION method
  - WORD-WRAP attribute

- For SpeedScript, the only valid options are: \textit{size-phrase}, INNER-CHARS, INNER-LINES, MAX-CHARS, NO-BOX, NO-WORD-WRAP.

\textbf{See also} \textit{SIZE phrase, VIEW-AS phrase}

\textbf{EMPTY TEMP-TABLE statement}

Empties a temp-table.
When you empty a temp-table that is defined as UNDO within a transaction, the AVM deletes the records individually. This is less efficient than emptying the temp-table outside the transaction, where the AVM deletes all records in the temp-table as a unit.

**Note:** This statement corresponds to the `EMPTY-TEMP-TABLE( )` method.

### Syntax

```
EMPTY TEMP-TABLE temp-table-name [ NO-ERROR ]
```

**temp-table-name**

The name of the temp-table.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the `ERROR-STATUS` system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the `ERROR-STATUS:ERROR` attribute to see if the AVM raised the ERROR condition.
- Check if the `ERROR-STATUS:NUM-MESSAGES` attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block **without** a CATCH end block treat errors as warnings and do not raise ERROR, do not set the `ERROR-STATUS:ERROR` attribute, but do add messages to the `ERROR-STATUS` system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block **with** a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the `ERROR-STATUS` system handle.
- Use `ERROR-STATUS:GET-MESSAGE( message-num )` to retrieve a particular message, where `message-num` is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.
- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the `ERROR-STATUS` system handle. Also, if errors raised in the block are not handled
by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

EMPTY-TEMP-TABLE( ) method

### ENABLE statement

Enables input for one or more field-level and child frame widgets within a frame.

#### Data movement

![Diagram of data movement]

#### Syntax

```plaintext
ENABLE [ UNLESS-HIDDEN ]
{ ALL [ EXCEPT field ... ]
  | { field [ format-phrase ] [ WHEN expression ]
  | TEXT ( { field [ format-phrase ]
  | [ WHEN expression ] } ... )
  | constant [ AT n | TO n ]
  | BGCOLOR expression ]
  | DCOLOR expression ]
  | FGCOLOR expression ]
  | FONT expression ]
  | PFCOLOR expression ]
  | VIEW-AS TEXT ]
  | SPACE [ ( n ) ]
  | SKIP [ ( n ) ]
  } ... ]
[ IN WINDOW window ] [ frame-phrase ]
```
ENABLE statement

ALL [ EXCEPT field ...]

Specifies that all field-level widgets for a frame are enabled, except those you list.

UNLESS-HIDDEN

Restricts ENABLE to fields whose HIDDEN attribute is FALSE.

field

Specifies the name of the field, variable, or widget you want to enable. Remember that the ENABLE statement accepts input only and stores it in the screen buffer. The underlying record buffer of a field or variable is unaffected unless you ASSIGN the value.

In array fields, array elements with constant subscripts are treated just like any other field. Array fields with no subscripts or array fields in the FORM statement are expanded as though you had entered the implicit elements. See the DISPLAY statement reference entry for information on how array fields with expressions as subscripts are handled.

---

**Note:** You cannot enable unfixed indeterminate array variables.

format-phrase

Specifies one or more frame attributes for a field, variable, or expression. For more information on format-phrase, see the Format phrase reference entry.

WHEN expression

Enables the field only if expression has a value of TRUE when the ENABLE statement is executed. Here, expression is a field name, variable name, or expression that evaluates to a LOGICAL value.

TEXT

Defines a group of character fields or variables (including array elements) to use automatic text-wrap. The TEXT option works only with character fields. When you insert data in the middle of a TEXT field, the AVM wraps data that follows into the next TEXT field, if necessary. If you delete data from the middle of a TEXT field, the AVM wraps data that follows into the empty area.

If you enter more characters than the format for the field allows, the AVM discards the extra characters. The character fields must have formats in the form x(n). A blank in the first column of a line marks the beginning of a paragraph. Lines within a paragraph are treated as a group and will not wrap into other paragraphs.

constant [ AT n | TO n ] [ BGCOLOR expression ] [ DCOLOR expression ]
[ FGCOLOR expression ] [ FONT expression ] [ PFCOLOR expression ]
[ VIEW-AS TEXT ]

Specifies a constant (literal) value that you want displayed in the frame. If you use the AT option, n is the column in which you want to start the display. If you use the TO option, n is the column in which you want to end the display. You can use the BGCOLOR and FGCOLOR options in graphical interfaces to define the foreground and background colors to use when the constant is displayed. Similarly, you can use the DCOLOR and PFCOLOR options in character interfaces to define the prompt and display colors to use...
when the constant is displayed. The font option, for both character and graphical interfaces, defines the font used. If you use the VIEW-AS TEXT option, the constant is displayed as a text widget rather than a fill-in field.

**SPACE [ (n) ]**

Identifies the number (n) of blank spaces to insert after the field displays. The n can be 0. If the number of spaces you specify is more than the spaces left on the current line of the frame, the AVM starts a new line and discards any extra spaces. If you do not use this option or n, the AVM inserts one space between items in the frame.

**SKIP [ (n) ]**

Identifies the number (n) of blank lines to insert after the field is displays. The n can be 0. If you do not use this option, the AVM does not skip a line between expressions unless the expressions do not fit on one line. If you use the SKIP option, but do not specify n, or if n is 0, the AVM starts a new line unless it is already at the beginning of a new line.

`^`

Tells the AVM to ignore an input field when input is being read from a file.

**IN WINDOW window**

Specifies the window in which the widgets are enabled. The window parameter must be the name of a currently defined window or an expression that evaluates to the handle for a currently defined window.

**frame-phrase**

The frame that contains the widgets to enable. If you omit frame-phrase, the default frame for the current block is assumed. For more information on frame-phrase, see the Frame phrase reference entry.

**Example**

The following example enables the CustNum field and the Quit button in the main procedure. If you press GO in the CustNum field and successfully find a record, the trigger disables the CustNum field and enables the CreditLimit field and the Save and Undo buttons. If you choose Save or Undo, the CHOOSE trigger disables the buttons and enables the CustNum field again. Note that if you choose the Save button, the trigger must execute an ASSIGN statement to set the value in the underlying database field.
For field representation widgets, the ENABLE statement lets you change the widget’s SCREEN-VALUE. If you want to save changes to the field itself, you must subsequently use the ASSIGN statement.

During data entry, a validation expression defined for the field in the database or in a Format phrase executes only if the widget associated with the field receives input focus. Use the VALIDATE( ) method to execute a validation expression defined for a field regardless of whether it receives input focus or not.

If you invoke the ENABLE statement for a frame, the AVM brings the frame into view unless the HIDDEN attribute for the frame or one of its ancestor frames or windows is TRUE.

If you invoke the ENABLE statement for the parent frame of a frame family, the field representation widgets and descendant frames owned by the parent frame are all enabled.
However, the field representation widgets of the descendant frames remain disabled and visually insensitive. To enable field representation widgets in the descendant frames and make them sensitive, you must invoke ENABLE statements for each of the descendant frames.

- If you specify the KEEP-TAB-ORDER option for a frame, the ENABLE statement has no affect on the tab order for the frame. Otherwise, the ENABLE statement can affect the tab order of widgets within the frame.

- The tab order for fields specified by the ENABLE statement replaces any conflicting tab order established by previous ENABLE statements or by previous settings of the FIRST-TAB-ITEM, LAST-TAB-ITEM, MOVE-AFTER-TAB-ITEM, or MOVE-BEFORE-TAB-ITEM attributes and methods.

- If you specify the ALL option with the ENABLE statement, the tab order of fields corresponds to the order they are specified in the frame definition. Also, the Data Dictionary field validations and help messages are compiled for all fields in the frame, including view-only fields (for example, text widgets).

- If you specify the ENABLE statement with field parameters, the specified fields are moved in the tab order to the end of the order specified for the original frame definition, and the tab order of each field corresponds to the order in which it is specified in the statement. The following code enables three widgets (a, b, and c) in frame A with the tab order d, e, f, a, b, and c:

```
DEFINE FRAME A a b c d e f.
ENABLE a b c WITH FRAME A.
```

**Note:** Note that widgets d, e, and f are not accessible until their SENSITIVE attributes are set to TRUE.

- If you use more than one ENABLE statement to enable widgets within a frame, each widget is added to the end of the tab order as it is enabled. For example, the following code enables three widgets in a frame:

```
ENABLE a.
ENABLE b.
ENABLE c.
```

This code sets the tab order as a b c. Rearranging the ENABLE statements changes the tab order.

- For SpeedScript, these options are invalid: BGCOLOR, DCOLOR, FGCOLOR, FONT, IN-WINDOW.

**See also** DISABLE statement, WAIT-FOR statement (ABL only)
ENCODE function

Encodes a source character string and returns the encoded character string result.

Syntax

```plaintext
ENCODE ( expression )
```

expression

An expression that results in a character string value. If you use a constant, you must enclose it in quotation marks (" ").

Example

This procedure uses the ENCODE function to disguise a password that the user enters, and then displays the encoded password:

```plaintext
r-encode.p
```

```plaintext
DEFINE VARIABLE password AS CHARACTER NO-UNDO FORMAT "x(16)".
DEFINE VARIABLE id AS CHARACTER NO-UNDO FORMAT "x(12)".
DEFINE VARIABLE n-coded-p-wrd AS CHARACTER NO-UNDO FORMAT "x(16)".

SET id LABEL "Enter user id" password LABEL "Enter password" BLANK WITH CENTERED SIDE-LABELS.

n-coded-p-wrd = ENCODE(password).

DISPLAY n-coded-p-wrd LABEL "Encoded password".
```

Notes

- You can use the ENCODE function to encode a string that contains double-byte characters.
- The ENCODE function performs a one-way encoding operation that you cannot reverse. It is useful for storing scrambled copies of passwords in a database. It is impossible to determine the original password by examining the database. However, a procedure can prompt a user for a password, encode it, and compare the result with the stored, encoded password to determine if the user supplied the correct password.
- In order to ensure reliable results, the original encoding and any subsequent encoded comparisons must run in the same code page. In environments with multiple code pages, Progress Software Corporation strongly recommends that programs use the CODEPAGE-CONVERT function so that occurrences of the ENCODE function related to the same strings run in the same code page.
- The output of the ENCODE function is 16 characters long. Make sure the target field size is at least 16 characters long.

encrypt function

Converts source data into a particular format, and returns a MEMPTR containing the encrypted data (a binary byte stream).
Note: You must use the same cryptographic algorithm, initialization vector, and encryption key values to encrypt and decrypt the same data instance.

Syntax

```
```

`data-to-encrypt`

The source data to encrypt. The value may be of type CHARACTER, LONGCHAR, RAW, or MEMPTR.

`encrypt-key`

An optional RAW expression that evaluates to the name of the encryption key (a binary value) to use in encrypting the specified data. If you specify the Unknown value (?), the current value of the SYMMETRIC-ENCRYPTION-KEY attribute is used. If the value of the SYMMETRIC-ENCRYPTION-KEY attribute is also the Unknown value (?), the AVM generates a run-time error.

You can generate this encryption key, based on the PKCS#5/RFC 2898 standard, by using either the GENERATE-PBE-KEY function or the GENERATE-RANDOM-KEY function.

Note: If you use the GENERATE-RANDOM-KEY function to generate an encryption key, be sure to invoke the function before invoking the ENCRYPT function (not within the ENCRYPT function, which would render the key irretrievable).

The AVM compares the size of the specified encryption key to the key size specified by the cryptographic algorithm. If the key sizes are inconsistent, the AVM generates a run-time error.

You are responsible for generating, storing, and transporting this value.

`iv-value`

An optional RAW expression that evaluates to an initialization vector value to use with the specified encryption key in the encryption operation. Using an initialization vector value increases the strength of the specified encryption key (that is, it makes the key more unpredictable). If you specify the Unknown value (?), the current value of the SYMMETRIC-ENCRYPTION-IV attribute is used.

`algorithm`

An optional CHARACTER expression that evaluates to the name of the symmetric cryptographic algorithm to use in encrypting the specified data instance. If you specify the Unknown value (?), the current value of the SYMMETRIC-ENCRYPTION-ALGORITHM attribute is used.

For a list the supported cryptographic algorithms, see the SYMMETRIC-SUPPORT attribute reference entry.

See also

DecrypT function, SECURITY-POLICY system handle
END statement

Indicates the end of a block started with a CASE, CATCH, CLASS, CONSTRUCTOR, DESTRUCTOR, DO, FINALLY, FOR, FUNCTION, INTERFACE, METHOD, PROCEDURE, or REPEAT statement or the end of an EDITING phrase, Trigger phrase, or the implementation of a GET or SET property accessor.

Syntax

```
END [ CASE | CATCH | CLASS | CONSTRUCTOR | DESTRUCTOR | FINALLY |
      FUNCTION | GET | INTERFACE | METHOD | PROCEDURE | SET | TRIGGERS ]
```

An option that can appear following any END statement that terminates the block for a statement or phrase that is specified with the same name.

Example

This procedure contains two blocks, each ending with the END statement:

```
r-end.p
```

```
FOR EACH Customer NO-LOCK:
FOR EACH Order OF Customer NO-LOCK:
   DISPLAY Order WITH 2 COLUMNS.
END.
```

Notes

- Two blocks, the CATCH block and the FINALLY block, are called end blocks because they must appear after the last line of executable code and before the END statement. CATCH blocks must appear before FINALLY blocks. See the entries for these two blocks for information about usage.
- If you do not use any END statements in a procedure, ABL assumes that all blocks end at the end of the procedure.
- If you use any END statements in a procedure, you must use one END statement for every block in the procedure.

ENTERED function

Checks whether a frame field has been modified during the last INSERT, PROMPT-FOR, SET, or UPDATE statement for that field, and returns a TRUE or FALSE result.

Note: Does not apply to SpeedScript programming.
Syntax

```
[ FRAME frame ] field ENTERED
```

The name of the frame field you are checking. If you omit the FRAME option, the field name must be unambiguous.

Example

This procedure goes through the Customer table and prompts the user for a new CreditLimit value. The ENTERED function tests the value the user enters. If the user enters a new value, the procedure displays the old and new CreditLimit values. If the user enters the same or no value, the value does not change.

```
DEFINE VARIABLE new-max NO-UNDO LIKE Customer.CreditLimit.
FOR EACH Customer:
  DISPLAY Customer.CustNum Customer.Name Customer.CreditLimit
  LABEL "Current credit limit"
  WITH FRAME a 1 DOWN ROW 1.
  SET new-max LABEL "New credit limit"
  WITH SIDE-LABELS NO-BOX ROW 10 FRAME b.
  IF new-max ENTERED THEN DO:
    IF new-max <> Customer.CreditLimit THEN DO:
      DISPLAY "Changing Credit Limit of" Customer.Name SKIP
      "from" Customer.CreditLimit "to" new-max
      WITH FRAME c ROW 15 NO-LABELS.
      Customer.CreditLimit = new-max.
      NEXT.
    END.
  END.
  DISPLAY "No Change In Credit Limit" WITH FRAME d ROW 15.
END.
```

Notes

- If you type blanks in a field where data has never been displayed, the ENTERED function returns FALSE, a SET or ASSIGN statement does not update the underlying field or variable. Also, if the AVM has marked a field as entered, and the PROMPT-FOR statement prompts for the field again and you do not enter any data, the AVM no longer considers the field entered.

- If you have changed the field’s window value since the last INSERT, PROMPT-FOR, SET, or UPDATE statement on that field, the ENTERED function returns FALSE. For example, if you use the DISPLAY statement to change the value of the field, ENTERED no longer returns TRUE.

- Before referencing a widget with the ENTERED function, you must scope the frame that contains that widget. For example, the following code does not compile:
The DEFINE FRAME statement does not scope the frame. Therefore, the reference to the ENTERED function in the trigger cannot be evaluated. To fix the problem, reference the frame in a DISPLAY statement before the ON statement.

See also  NOT ENTERED function

ENTRY function

Returns a character string (CHARACTER or LONGCHAR) entry from a list based on an integer position.

Syntax

ENTRY ( element , list [ , character ] )

element

An integer value that corresponds to the position of a character string in a list of values. If the value of element does not correspond to an entry in the list, the AVM raises the ERROR condition. If the value of element is the Unknown value (?), ENTRY returns the Unknown value (?). If element is less than or equal to 0, or is larger than the number of elements in list, ENTRY returns an error.

list

A list of character strings separated with a character delimiter. The list can be a variable of type CHARACTER or LONGCHAR. If the value of list is the Unknown value (?), ENTRY returns the Unknown value (?).

character

A delimiter you define for the list. The default is a comma. This allows the ENTRY function to operate on non-comma-separated lists. If you use an alphabetic character, this delimiter is case sensitive.

Examples

This procedure returns the day of the week that corresponds to a date the user enters. The WEEKDAY function evaluates the date and returns, as an integer, the day of the week for that date. The ENTRY function uses that integer to indicate a position in a list of the days of the week.
This is an example of a list separated by dashes instead of commas (the result is “helvetica”):

The next procedure looks up UNIX login IDs in a small password array and returns the name of the user:

The ENTRY function is double-byte enabled. It can return an entry that contains double-byte characters from a specified list and the character delimiter can be a double-byte character.

The ENTRY function is double-byte enabled. It can return an entry that contains double-byte characters from a specified list and the character delimiter can be a double-byte character.

Note
The ENTRY function is double-byte enabled. It can return an entry that contains double-byte characters from a specified list and the character delimiter can be a double-byte character.

See also
LOOKUP function

ENTRY statement

Used on the left-hand side of an assignment to set the _n_th element to some value.
ENTRY statement

Syntax

ENTRY ( element, list [ , character ] ) = expression

**element**

An integer value that corresponds to the position of a character string in a list of values. If the value of `element` does not correspond to an entry in the list, the AVM raises the ERROR condition. If the value of `element` is the Unknown value (?), ENTRY returns the Unknown value (?). If `element` is less than or equal to 0, or is larger than the number of elements in `list`, ENTRY returns an error.

**list**

A list of character strings separated with a character delimiter. The `list` can be a variable of type CHARACTER or LONGCHAR. If the value of `list` is the Unknown value (?), ENTRY returns the Unknown value (?).

**character**

A delimiter you define for the list. The default is a comma. This allows functions to operate on non-comma-separated lists. The delimiter must be only a single character. If you specify a string of more than one character, only the first character is used. If you specify a null string (""), a space character is used as the delimiter. If you use an alphabetic character, this delimiter is case sensitive.

**expression**

A constant, field name, variable name, or expression that results in a character string whose value you want to store in the `n`th element in a list. ABL does not pad or truncate expression.

**Example**

This procedure uses three ENTRY statements:

```plaintext
DEFINE VARIABLE num-recs AS INTEGER NO-UNDO.
DEFINE VARIABLE msg-txt  AS CHARACTER NO-UNDO INITIAL "There are <x> records in the table.".
/* Count the records. */
FOR EACH Customer NO-LOCK:
   num-recs = num-recs + 1.
END.

/* If there is only one record, make the message singular. */
IF num-recs = 1 THEN
   ASSIGN
      ENTRY(2,msg-txt," ") = "is"
      ENTRY(4,msg-txt," ") = "record".
/* Insert the record count into the string. */
ENTRY(3,msg-txt," ") = STRING(num-recs).
MESSAGE msg-txt.
```

r-ent-eq.p

```plaintext
DEFINE VARIABLE num-recs AS INTEGER NO-UNDO.
DEFINE VARIABLE msg-txt  AS CHARACTER NO-UNDO INITIAL "There are <x> records in the table.".
/* Count the records. */
FOR EACH Customer NO-LOCK:
   num-recs = num-recs + 1.
END.

/* If there is only one record, make the message singular. */
IF num-recs = 1 THEN
   ASSIGN
      ENTRY(2,msg-txt," ") = "is"
      ENTRY(4,msg-txt," ") = "record".
/* Insert the record count into the string. */
ENTRY(3,msg-txt," ") = STRING(num-recs).
MESSAGE msg-txt.
```
Note  
The ENTRY statement is double-byte enabled. It can insert an entry that contains double-byte characters into a specified list and the character delimiter can be a double-byte character.

See also  
ENTRY function

---

**Enumeration member access**  
*(Windows only; GUI for .NET only)*

References a .NET enumeration member in order to read its value.

**Syntax**  

\[
\text{type-name} : \text{enum-member}
\]

- **type-name**  
The type name of a .NET enumeration whose member you want to access. Specify an enumeration type name using the syntax as described in the *Type-name syntax reference* entry. With an appropriate **USING** statement, you can specify an unqualified .NET enumeration name.

- **enum-member**  
  Specifies a name that identifies a specific member of the enumeration. In ABL, an enumeration member is an object that represents a constant value with a specific underlying data type defined for the enumeration. All members of an enumeration share the same underlying data type. Wherever you reference an enumeration member, ABL references the member object, not the defined constant value that the specified member represents. However, because a .NET enumeration is a value type, when you pass the enumeration member to a .NET method parameter or assign it to or from a .NET property or data member, ABL automatically converts between the .NET value and the ABL object that represents it.

**Example**  
To set the background color of a button (button1) to the known system color, aqua, you might enter this ABL code to set the **BackColor** button property to the value of the appropriate **System.Drawing.KnownColor** enumeration member:

\[
\text{button1:BackColor} = \text{System.Drawing.KnownColor:Aqua}.
\]

**Notes**  
- A .NET enumeration can be an inner member of a class or its own type. For more information on referencing enumerations, see the *Type-name syntax reference* entry.

- Because, in ABL, .NET enumeration members are objects, you cannot operate on them directly using ABL operators the way .NET languages use built-in operators to operate on enumeration values. To allow you to perform .NET enumeration operations, ABL supports an OpenEdge .NET class, Progress.Util.EnumHelper. The *Progress.Util.EnumHelper class* contains static methods that you can use to perform the relational, arithmetic, and bit-wise operations commonly applied to enumeration members in .NET.

**See also**  
Progress.Util.EnumHelper class
EQ or = operator

Returns a TRUE value if two expressions are equal.

Syntax

```
expression { EQ | = } expression
```

expression

A constant, field name, variable name, or expression. The expressions on either side of the EQ or = must be of the same data type, although one might be an integer and the other a decimal.

Example

This procedure prompts for the initials of a sales rep. The FOR EACH block reads all the order records for that sales rep. The DISPLAY statement displays information from each of the retrieved records.

```
r-eq.p

PROMPT-FOR Order.SalesRep WITH SIDE-LABELS CENTERED.
FOR EACH Order NO-LOCK WHERE Order.SalesRep EQ INPUT Order.SalesRep:
  DISPLAY Order.OrderNum Order.CustNum Order.OrderDate Order.PromiseDate Order.ShipDate
  WITH CENTERED.
END.
```

Notes

- By default, the AVM uses the collation rules you specify to compare characters and sort records. The collation rules specified with the Collation Table (-cpcoll) startup parameter take precedence over a collation specified for any database the AVM accesses during the session, except when the AVM uses or modifies pre-existing indexes. If you do not specify a collation with the -cpcoll startup parameter, the AVM uses the language collation rules defined for the first database on the command line. If you do not specify a database on the command line, the AVM uses the collation rules with the default name "basic" (which might or might not exist in the convmap.cp file).

- You can compare character strings with EQ. Most character comparisons are case insensitive in ABL. That is, upper-case and lower-case characters have the same sort value. However, it is possible to define fields and variables as case sensitive (although it is not advised, unless strict ANSI SQL adherence is required). If either expression is a field or variable defined as case sensitive, the comparison is case sensitive and “Smith” does not equal “smith”.

- Characters are converted to their sort code values for comparison. Using the default case-sensitive collation table, all uppercase letters sort before all lowercase letters (for example, a is greater than Z, but less than b.) Note also that in character code uppercase A is less than [ , \, ^, _, and ' , but lowercase a is greater than these.

- If one of the expressions has an Unknown value (?) and the other does not, the result is FALSE. If both have the Unknown value (?), the result is TRUE. However, for SQL, if the value of either or both expressions is the Unknown value (?), then the result is the Unknown value (?).
• The equal comparison ignores trailing blanks. Thus, “abc” is equal to “abc       “. However, leading and embedded blanks are treated as characters and “     abc” is not equal to “abc”.

• You cannot compare data of different DATE, DATETIME, and DATETIME-TZ data types to each other using EQ. You must first convert different date and datetime data types to the same data type before doing a comparison between them.

• You can use EQ to compare one BLOB field to another. The AVM performs a byte-by-byte comparison.

• You can use EQ to compare a LONGCHAR variable to another LONGCHAR or CHARACTER variable. The variable values are converted to -cpinternal for comparison and must convert without error, or the AVM raises a run-time error.

• You can use EQ to compare a CLOB field only to the Unknown value (?)..

**ERROR function**

Indicates whether an error occurred during a FILL or SAVE-ROW-CHANGES operation on the specified ProDataSet temp-table buffer.

**Syntax**

```
ERROR( buffer-name )
```

*buffer-name*

The name of a ProDataSet temp-table buffer.

**Notes**

• The ERROR function corresponds to the ERROR attribute.

• You can invoke the ERROR function from within a WHERE clause (unlike the corresponding attribute).

**ETIME function**

Returns, as an INT64 value, the time (in milliseconds) elapsed since the ABL session began or since ETIME (elapsed time) was last set to 0. To set ETIME to 0, pass it a positive logical value, such as YES or TRUE.

**Syntax**

```
ETIME [ ( logical ) ]
```

*logical*

A logical value, such as YES or TRUE. The default value is NO.

**Examples**

This procedure displays the time that elapsed since you began your ABL session:
This procedure sets ETIME to 0, runs a procedure called applhelp.p, and displays the elapsed time, which, in this case, equals the time required to execute applhelp.p:

```
DEFINE VARIABLE a AS INT64 NO-UNDO.
DO:
  a = ETIME(yes).
  RUN applhelp.p.
  DISPLAY ETIME.
END.
```

**Notes**

- ETIME is accurate to at least one-sixtieth of a second, but accuracy varies among systems.
- ABL resets ETIME during startup, not immediately after you enter the pro command. Therefore, the time returned is only an approximation of the time elapsed since your session began.

ADD-INTERVAL function, DATE function, DATE-FORMAT attribute, DATETIME function, DATETIME-TZ function, DAY function, INTERVAL function, ISO-DATE function, MONTH function, MTIME function, NOW function, TIME function, TIME-SOURCE attribute, TODAY function, WEEKDAY function, YEAR function, YEAR-OFFSET attribute

**EXP function**

Returns the result of raising a number to a power. The number is called the base and the power is called the exponent.

**Syntax**

```
EXP ( base , exponent )
```

**Base**

A constant, field name, variable name, or expression that evaluates to a numeric value.

**Exponent**

A numeric expression.

**Example**

This procedure calculates how much a principal amount invested at a given compounded annual interest rate grows over a specified number of years:
Notes

- After converting the base and exponent to the floating-point format, the EXP function uses standard system library routines. On some machines, these routines do not handle large numbers well and might cause your terminal to hang. Also, because the calculations are done in floating-point arithmetic, full decimal precision is not possible beyond 1-12 significant digits on most machines.

- The EXP function is precise to approximately 10 decimal points.

EXPORT statement

Converts data to a standard character format and displays it to the current output destination (except when the current output destination is the screen) or to a named output stream. You can use data exported to a file in standard format as input to other ABL procedures.

Syntax

```
EXPORT [ STREAM stream | STREAM-HANDLE handle ] [ DELIMITER character ]
   { expression ...
     | record [ EXCEPT field ... ]
   }
[ NO-LOBS ]
```
See the chapter on alternate I/O sources in *OpenEdge Development: Programming Interfaces* for more information on streams and stream handles.

**DELIMITER character**

The character to use as a delimiter between field values. The `character` parameter must be a quoted `single` character. The default is a space character.

If you specify more than one character as a delimiter, ABL uses the first character as the delimiter.

**expression . . .**

One or more expressions that you want to convert into standard character format for display to an output destination.

**record**

The name of the record buffer with fields that you want to convert into the standard character format to display to an output destination.

To use EXPORT with a record in a table name used in multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

**EXCEPT field . . .**

The AVM exports all fields except those fields listed in the EXCEPT phrase.

**memptr**

A variable of data type MEMPTR that contains the text to export. The EXPORT statement may contain a MEMPTR in its field list as long as it is the only field in the list.

**longchar**

A variable of data type LONGCHAR that contains the text to export. The EXPORT statement may contain a LONGCHAR in its field list as long as it is the only field in the list.

**NO-LOBs**

Directs the AVM to ignore large object data when exporting records that contain BLOB or CLOB fields.

**Examples**

This procedure converts the data in the Customer table into standard character format and sends that data to the customer.d file:

```
r-expnt.p

OUTPUT TO customer.d.
FOR EACH Customer NO-LOCK:
    EXPORT Customer.
END.
OUTPUT CLOSE.
```
The next procedure shows how each EXPORT statement creates one line of data (that is, fields are not wrapped onto several lines):

**r-exp12.p**

```plaintext
OUTPUT TO custdump.
FOR EACH Customer NO-LOCK:
END.
OUTPUT CLOSE.
```

That procedure creates a text file, `custdump`, with one line for each Customer. This is a typical line of output:

```
1 "Lift Line Skiing" 58400
```

Use the DELIMITER option to specify a character other than a space to separate fields in the output file. For example, the following procedure uses a semicolon:

**r-cstout.p**

```plaintext
OUTPUT TO custdump2.
FOR EACH Customer NO-LOCK:
END.
OUTPUT CLOSE.
```

This is a typical line of output from this code:

```
1;"Lift Line Skiing";58400
```

The following example displays using a MEMPTR to EXPORT mixed character and binary data:

**r-expmem.p**

```plaintext
/* Character and binary data mixed */
DEFINE VARIABLE z AS MEMPTR NO-UNDO.
ASSIGN
    SET-SIZE(z) = 100
    PUT-STRING(z,1) = "hi there"
    PUT-LONG(z,10) = 235
    PUT-STRING(z,14) = "afterint"
    PUT-LONG(z,22) = 76.
OUTPUT TO abc BINARY NO-CONVERT.
EXPORT z.
OUTPUT CLOSE.
```

**Notes**

- The EXPORT statement must follow an OUTPUT TO statement, which redirects the output destination.
• Other procedures can use the data exported with the EXPORT statement as input by reading the file with the INSERT, PROMPT-FOR, SET, UPDATE or IMPORT statements, naming one field or variable to correspond to each data element.

• The data is in a standard format to be read back into ABL. All character fields are enclosed in quotes (""), and quotes contained in the data you are exporting are replaced by two quotes ("""). A single space separates one field from the next. An Unknown value (?) is displayed as an unquoted question mark (?).

• There are no trailing blanks, leading zeros, or formatting characters (for example, dollar signs) in the data.

• ABL exports logical fields as the value YES or NO.

• A Format phrase with an EXPORT statement is ignored.

• If you use a single qualified identifier with the EXPORT statement, the Compiler first interprets the reference as dbname.tablename. If the Compiler cannot resolve the reference as dbname.tablename, it tries to resolve it as tablename.fieldname.

• When exporting fields, you must use table names that are different from field names to avoid ambiguous references. See the Record phrase reference entry for more information.

• When exporting RECID fields, you must explicitly state the RECID field name in the EXPORT statement.

• When exporting ROWID variables or fields in a work table, you must convert the ROWID variable or field to a character string using the STRING function.

• When exporting records that contain a BLOB or CLOB field, the AVM creates a separate object data file using a unique filename with a .blb extension and stores that filename in the BLOB or CLOB field of the exported record. (When importing records that contain a BLOB or CLOB field, the AVM uses this filename to locate the object data file associated with each record.) If the BLOB or CLOB field contains the Unknown value (?), the AVM stores the Unknown value (?) in the BLOB or CLOB field of the exported record, and does not create an object data file. If the BLOB or CLOB field contains a zero-length object, the AVM creates a zero-length object data file. The AVM raises the ERROR condition if an object data file cannot be created.

• The EXPORT statement creates large object data files in the directory specified as the output destination in the OUTPUT TO statement, by default. You can use the LOB-DIR option on the OUTPUT TO statement to specify the directory in which the EXPORT statement creates the BLOB and CLOB data files.

• Use the NO-LOBS option with the EXPORT statement to ignore large object data when exporting records that contain BLOB or CLOB fields. When you specify the NO-LOBS option, the AVM stores the Unknown value (?) in the BLOB or CLOB field of the exported records and does not create the associated object data files.

• When exporting DATETIME and DATETIME-TZ data, the data format is fixed and conforms to the ISO 8601 standard for date/time representations (YYYY-MM-DDTHH:MM:SS.SSS+HH:MM). For DATETIME, there is no time zone offset.
• If you use the DELIMITER option of the EXPORT statement to specify a delimiter other than a space character, you must specify the same delimiter character in a subsequent IMPORT statement that loads the data.

• EXPORT is sensitive to the Date format (-d), Century (-yy), and European numeric (-E) startup parameters. When loading data with the IMPORT statement, use the same settings that you used with the EXPORT statement.

• In the MEMPTR version of the EXPORT statement, the MEMPTR’s size will determine how much is written to the file. If the size of a MEMPTR is 100, and it only contains a string of length 10, the entire 100 bytes will still be written to the file. The PUT-BYTES statement and GET-BYTES function may be used to move portions of MEMPTRs to areas with varying sizes. You can read and write parts of a file by using MEMPTRs of varying sizes, and multiple EXPORT/IMPORT statements on the same file.

• When dealing with Unicode CLOB and LONGCHAR variables, avoid using the EXPORT statement. The AVM uses the UTF-8 codepage for all Unicode EXPORTs. Use the COPY-LOB statement to avoid this conversion.

• Never use APPEND while EXPORTing a LONGCHAR variable.

See also
COPY-LOB statement, DEFINE STREAM statement, DISPLAY statement, IMPORT statement, OUTPUT CLOSE statement, OUTPUT TO statement, PUT statement, Stream object handle, STRING function

Expression

A combination of one or more terms and operators that evaluate to a single value of a specific data type.

Syntax

\[
[ \text{unary-operator} ] [ ( ) \{ \text{term} | \text{term binary-operator term} \} [ ) ]
\]

unary-operator

Any ABL unary operator that can precede the specified term, including:

• + Unary positive operator
• – Unary negative operator
• NOT operator

( 

Begins a group of one or more terms and operators that are evaluated together before any terms or operators to the left of the ‘(’. If specified, the group must be terminated with a ‘)’.

term

Any one of the following ABL elements that represents or returns a value with a data type that is compatible with the expression data type, including:

• A literal (constant) value represented according to its data type (Data types)
• A database or temp-table field reference (Record phrase, DEFINE TEMP-TABLE statement)

• A reference to a variable scoped to the current procedure, user-defined function, or method of a class, or to an accessible class-based variable data member, including a subscripted or unsubscripted array reference (DEFINE VARIABLE statement, Class-based data member access)

• A reference to a parameter (of any mode) defined for the current procedure, user-defined function, or method of a class, including a subscripted or unsubscripted array reference (DEFINE PARAMETER statement)

• A reference to a readable class-based property or COM property, including a subscripted or unsubscripted array reference (DEFINE PROPERTY statement, Class-based property access, Accessing COM object properties and methods)

• Readable handle attribute reference (Accessing handle attributes and methods)

• Readable system handle reference (Handle Reference)

• An ABL built-in or user-defined function call (FUNCTION statement)

• A handle method, non-VOID COM method, or non-VOID class-based method call (Accessing handle attributes and methods, Accessing COM object properties and methods, Class-based method call)

• An Expression (recursive)

Note that each term of the expression can itself be formed from an expression, resulting in multiple possible combinations of basic terms and operators, with or without grouping parentheses. Note that each of these elements, except for a more complex Expression, represents a basic term of the expression.

**binary-operator**

Any ABL binary operator that can separate two term elements, each of which must have a data type that is compatible with an expression that can result when applying the specified binary-operator to the specified term elements, including the:

• + Addition operator

• + Concatenation operator

• + Date addition operator

• + Datetime addition operator

• – Subtraction operator

• – Date subtraction operator

• – Datetime subtraction operator

• * Multiplication operator

• / Division operator
Expression

- AND operator
- BEGINS operator
- EQ or = operator
- GE or >= operator
- GT or > operator
- LE or <= operator
- LT or < operator
- MATCHES operator
- MODULO operator
- NE or <> operator
- OR operator

Terminates a group of one or more terms and operators that are evaluated together before any terms or operators to the right of the ‘)’.

For information on the precedence of operator evaluation, see Table 36.

Example

The procedure, r-expression.p, evaluates an expression to identify the value of an element in an ABL single-dimensional array (iArray) that is specified using two-dimensional coordinates (iDim1 and iDim2):

r-expression.p

```
DEFINE VARIABLE iDim1 AS INTEGER NO-UNDO.
DEFINE VARIABLE iDim2 AS INTEGER NO-UNDO.
DEFINE VARIABLE iDim1Extent AS INTEGER NO-UNDO INITIAL 3.
DEFINE VARIABLE iDim2Extent AS INTEGER NO-UNDO INITIAL 5.
DEFINE VARIABLE iArray AS CHARACTER NO-UNDO EXTENT 15 INITIAL 
  ["A","B","C","D","E","F","G","H","I","J","K","L","M","N","O"]. /* iDim1 = 1 */
DO iDim1 = 1 TO iDim1Extent:
  DO iDim2 = 1 TO iDim2Extent:
    MESSAGE "iArray[" iDim1 "," iDim2 "]" = "
iArray[ iDim2 + (iDim1 - 1) * iDim2Extent ] VIEW-AS ALERT-BOX.
  END.
END.
```

This procedure contains several expressions in the DO statements as well as in the MESSAGE statement. The expression that evaluates the index on the term, iArray, using a two-dimensional coordinate is shown in bold. This expression first evaluates the subtraction (-) operation in parentheses, then, in order by operator precedence, evaluates the multiplication (*) operation followed by the addition operation (+).

Notes

- A series of terms and operators in an expression, with no grouping parentheses (‘(’ and ‘)’), evaluate in an order of precedence determined by the operators. Thus, operators of
higher precedence evaluate before operators of lower precedence, and operators of the same precedence evaluate in order from left to right. Otherwise, a series of terms and operators within a particular grouping parentheses evaluate according to their precedence before any series of terms and operators outside that grouping parentheses. Table 36 shows the order of precedence for ABL operators identified by function and symbol.

<td>OR</td>
</tr>
</tbody>
</table>

Note that before the ABL Virtual Machine (AVM) applies the operators to an expression, it evaluates all the basic terms (variables, properties, methods, functions, etc.) of the expression individually from left to right.

- If you do not include any white space in expressions, ABL does not distinguish between a hyphen (-) used as an operator and a hyphen used as part of an ABL built-in or user-defined element name. In order to enable ABL to identify a hyphen used as an operator, you must add at least one space between the hyphen and the term or terms that the operator evaluates.

- An expression of the appropriate data type can appear as a variable option of any ABL statement that takes an expression, except where specified. Expressions commonly appear in the Assignment (=) statement, ASSIGN statement, and as arguments to INPUT parameters of procedures, functions, and methods (Parameter passing syntax). Expressions cannot appear where a variable syntax option accepts only a quoted string, a
user-defined name (such as a procedure or variable name), or a compile-time constant. Other restrictions might also apply.

- You cannot directly reference a BLOB or CLOB database or temp-table field as a term in an expression, except as specifically provided in a given ABL statement or built-in function. Generally, you must first convert the BLOB or CLOB to a MEMPTR or LONGCHAR data type using the COPY-LOB statement, then use the result in the expression.

- When a run-time error occurs in any part of an expression, the AVM stops evaluating the expression and raises the ERROR condition on the statement that contains the expression. If the error occurs in a basic term of the expression, because the AVM first evaluates all the basic terms of an expression from left to right, all such terms (especially, methods and functions) prior to the term that raises ERROR will complete execution. However, any data element set to receive the result of the expression evaluation remains unchanged, for example, when the expression is on the right-hand side of an Assignment (=) statement or is passed to an INPUT parameter. The ERROR condition from an expression can be handled, like any statement error, as appropriate for the specified statement and block error processing, including use of statement NO-ERROR options, ON ERROR phrases, and CATCH statements to handle any error messages and error objects returned from the expression. For more information, see OpenEdge Development: Error Handling.

See also Assignment (=) statement, ASSIGN statement, CATCH statement, COPY-LOB statement, Data types, ERROR-STATUS system handle, Parameter passing syntax

EXTENT function

This function returns the extent of an array field or variable as an INTEGER value. More specifically, it returns:

- The constant or variable extent value for a field or variable defined as a determinate array
- The Unknown value (?) for a field or variable defined as an unfixed indeterminate array
- The extent for a field or variable defined as a fixed indeterminate array
- Zero for a field or variable that is not an array

Note: The EXTENT function corresponds to the EXTENT attribute.

Syntax

```
EXTENT ( array )
```

array

Any array field or variable.

Example

In the following example, the EXTENT function is used to set the limit of a DO loop that cycles through all elements of an array:
EXTENT statement

Fixes the extent (number of elements) for an unfixed indeterminate array variable or parameter. ABL treats the fixed indeterminate array as a determinate array consistent with its data type.

**Syntax**

```
EXTENT ( array ) = expression [ NO-ERROR ]
```

**array**

A CHARACTER expression that evaluates to the name of an unfixed indeterminate array variable or parameter.

**expression**

An INTEGER expression that evaluates to the extent value assigned to the array variable or parameter. The extent value can be any number between 1 and 28000, inclusive.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.
- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object.

---

**r-arrext.p**

```plaintext
DEFINE VARIABLE int_value AS INTEGER NO-UNDO EXTENT 3 INITIAL [1, 2, 3].
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE tot AS INTEGER NO-UNDO LABEL "The total is".

DO ix = 1 TO EXTENT(int_value):
    tot = tot + int_value[ix].
END.

DISPLAY tot.
```

**See also**

DEFINE VARIABLE statement, ENTRY function, EXTENT attribute, EXTENT statement
generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.
- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.
- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.
- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Example**

The following example defines an unfixed indeterminate array variable and fixes its dimension using the EXTENT statement:

```
DEFINE VARIABLE x AS INTEGER NO-UNDO EXTENT.
MESSAGE EXTENT(x). /* Function returns ? */
EXTENT(x) = 4. /* Statement fixes the extent to 4 */
MESSAGE EXTENT(x). /* Function returns 4 */
```

**Notes**

- You can also use the EXTENT statement to reset a fixed indeterminate array (that was previously defined as an unfixed indeterminate array) to its previously unfixed state by specifying the Unknown value (?) in expression.
- If you call the EXTENT statement attempting to fix the extent of a determinate or fixed indeterminate array variable or parameter, the AVM generates a run-time error. Consider first using the EXTENT function to determine if an array variable or parameter is already fixed.

**See also**

DEFINE PARAMETER statement, DEFINE VARIABLE statement, EXTENT attribute, EXTENT function, Parameter definition syntax
**FILL function**

Generates a character string made up of a character string that is repeated a specified number of times.

**Syntax**

```
FILL ( expression , repeats )
```

*expression*

An expression that yields a character value. This expression can contain double-byte characters.

*repeats*

A constant, field name, variable name, or expression with an integer value. The FILL function uses this value to repeat the *expression* you specify. If the value of *repeats* is less than or equal to 0, FILL produces a null string.

**Example**

This example procedure produces a bar chart that depicts each Customer’s balance as a percentage of the total of all outstanding balances. The first FOR EACH block accumulates the value of balance for each Customer, producing a total balance value for all Customers. The next FOR EACH block goes through the Customer table again, figuring each Customer’s balance as a percentage of the total.

```
r-fill.p
```

```
DEFINE VARIABLE fillchar AS CHARACTER NO-UNDO FORMAT "x" INITIAL ".".
DEFINE VARIABLE percentg AS INTEGER NO-UNDO FORMAT ">>9".

FOR EACH Customer NO-LOCK:
  ACCUMULATE Customer.Balance (TOTAL).
END.

DISPLAY "Percentage of Outstanding Balance" WITH CENTERED NO-BOX.

FOR EACH Customer NO-LOCK WHERE Customer.Balance > 0:
  FORM SKIP Customer.Name percentg LABEL "%" bar AS CHARACTER
    LABEL "  1  2  3  4  5  6  7  8  9 10 11 12 13 14 15 16 17"
    FORMAT "x(50)" WITH NO-BOX NO-UNDERLINE USE-TEXT.
    COLOR DISPLAY BRIGHT-RED bar.
  DISPLAY Customer.Name percentg FILL(fillchar,percentg * 3) @ bar.
END.
```

The FORM statement describes the frame layout, including the name, the percentage of total balance, and a bar across the top of the frame. (The bar variable is defined on-the-fly; it has no corresponding DEFINE VARIABLE statement at the top of the procedure. It is defined in the FORM statement and has its own label and format.) The DISPLAY statement following the FORM statement displays the bar variable. If the procedure is running on UNIX or on a monochrome PC monitor, the AVM ignores the COLOR BRIGHT-RED. However, if the procedure is running on a PC with a color monitor, the bar is displayed in BRIGHT-RED (a predefined color on the PC). The final DISPLAY statement displays the bars.
The `fillchar` assignment statement sets the fill character to asterisk (*). The FILL function generates a string made up of fill characters that is the percentage of total sales multiplied by three (each percentage point uses three fill characters).

**FINALLY statement**

Defines a final end block for any ABL block. An end block is an ABL block that can occur only within another block. The block containing the end block is known as the associated block. End-blocks must occur between the last line of executable code in the associated block and the END statement.

For any ABL block statement, the FINALLY statement defines an optional end block that contains ABL code to execute at the conclusion of all other processing in the associated block or once at the conclusion of each iteration of an associated iterating block. This is the syntax for the FINALLY statement and its related blocks:

**Syntax**

```
block-statements
   FINALLY:
       finally-logic
   END [ FINALLY ] .
   [ block-end-statement ]
```

*block-statements*

All of the statements of an enclosing associated ABL block, except for its *block-end-statement*. The enclosing associated block can be any ABL block, including another FINALLY block.

*finally-logic*

All statements allowed in a FINALLY block, which can include any valid ABL statement. For more information on FINALLY block execution, see the notes for this reference entry.

*block-end-statement*

For all associated ABL blocks except a main external procedure block, the END statement terminating the enclosing associated block of the FINALLY block. External procedure blocks have no terminating END statement.

**Examples**

As shown in r-finally01.p, the FINALLY block executes before any flow-of-control (LEAVE, NEXT, RETRY, RETURN, or THROW) options are executed for the associated block. For iterating blocks, the FINALLY block executes after each iteration of the block.
**r-finally01.p**

```plaintext
DO ON ERROR UNDO, LEAVE:
   /* Since Customer 1000 does not exist, the FIND statement raises ERROR and 
   execution goes to FINALLY block before the LEAVE option executes. */
   FIND Customer 1000.
   MESSAGE "This message never appears because of ERROR condition."
   VIEW-AS ALERT-BOX BUTTONS OK.

FINALLY:
   MESSAGE "Inside FINALLY block." VIEW-AS ALERT-BOX BUTTONS OK.
   /* LEAVE DO block here */
END FINALLY.
END. /* DO */
MESSAGE "Out of DO block." VIEW-AS ALERT-BOX BUTTONS OK.
```

In `r-finally02.p`, after ERROR is raised, execution goes to the CATCH block and then to the FINALLY block.

**r-finally02.p**

```plaintext
DO ON ERROR UNDO, LEAVE:
   /* Since Customer 1000 does not exist, the FIND statement raises ERROR and 
   execution goes to CATCH block. */
   FIND Customer 1000.
   MESSAGE "This message never appears because of ERROR condition."
   VIEW-AS ALERT-BOX BUTTONS OK.

CATCH eSysError AS Progress.Lang.SysError:
   /* Handler code for SysError condition */
   MESSAGE "Inside CATCH block." VIEW-AS ALERT-BOX BUTTONS OK.
   /* Execution goes to FINALLY before leaving DO block. */
END CATCH.

FINALLY:
   /* Your code */
   MESSAGE "Inside FINALLY block." VIEW-AS ALERT-BOX BUTTONS OK.
   /* LEAVE DO block here. */
END FINALLY.
END. /* DO */
MESSAGE "Out of DO block." VIEW-AS ALERT-BOX BUTTONS OK.
```

In `r-finally03.p`, after ERROR is raised, execution goes to the CATCH block, which re-throws the error. However, the FINALLY block executes before the error goes to the CATCH block associated with the procedure block.
Notes

- There can be only one FINALLY block in any associated block. The FINALLY statement must come after all other executable statements in the associated block. If the associated block contains CATCH statements, the FINALLY block must come after all CATCH blocks. Note that the FINALLY statement can be used in a block with no CATCH blocks.

- The FINALLY block executes as an end block of the associated block. This means that the FINALLY block cannot execute until the associated block executes. The FINALLY block executes once for each iteration of its associated block. This means you can only execute the FINALLY block during the execution of the associated block. The FINALLY block executes on success or failure of the associated block.

Thus, the FINALLY block executes:

- After successful execution of the associated block
- After each successful iteration of an iterating associated block
- After ERROR is raised in the associated block and a CATCH block handles the error
- After ERROR is raised in the associated block and no CATCH handles the error

The FINALLY block will not execute:

- If a STOP condition is raised
- If a QUIT statement is in effect

- The purpose of a FINALLY block is to hold clean-up code that must execute regardless of what else executed in the associated block. It can include code to delete objects and dynamic objects, write to logs, close outputs, and other routine tasks. Because it executes even if the ERROR condition is raised, the FINALLY block is also a useful part of a structured error handling scheme.
• Since it executes after an invoked CATCH block, the FINALLY block can also be used to perform common post-CATCH clean up tasks, rather than repeating common code in all the CATCH blocks present in the associated block.

• The transaction of the associated block is either complete (success) or undone (failure) when FINALLY executes. Therefore, any UNDO statement within the FINALLY block will only undo the work in the FINALLY block.

• The FINALLY block is an undoable block with implicit ON ERROR UNDO, THROW error handling. You cannot explicitly override the ON ERROR directive for a FINALLY block. If a statement within the FINALLY block raises ERROR, the FINALLY block will be undone, and ERROR will be raised in the block that encloses the associated block of the FINALLY block. Error is not raised in the associated block. Otherwise, infinite looping could occur.

A statement that raises ERROR within a FINALLY end block causes the following to occur:

a) UNDO the FINALLY block.

b) LEAVE the associated block.

c) THROW the error to the block enclosing the associated block.

The same behavior occurs for an explicit THROW statement in a FINALLY block.

• The code in any FINALLY block can contain explicit flow-of-control options: LEAVE, NEXT, RETRY, RETURN, or THROW. Since FINALLY is an undoable block, LEAVE, NEXT, and RETRY without a label apply to the FINALLY block itself and not to the associated block.

If you want LEAVE, NEXT, or RETRY to apply to the associated block, use label syntax with these statements. Flow of control statements in a FINALLY block override pending flow of control from a CATCH block.

• If the AVM detects a STOP or QUIT condition in the associated block, the FINALLY block will not run and the AVM processes the condition. If the associated block has an ON STOP or ON QUIT phrase, then the STOP or QUIT condition is handled and released by the time the AVM is ready to execute the FINALLY block, and the FINALLY block is executed. See the ON STOP and ON QUIT reference entries for a description of the STOP and the QUIT condition behavior and handling.

---

**FIND statement**

Locates a single record in a table and moves that record into a record buffer.

**Data movement**
Syntax

FIND [ FIRST | LAST | NEXT | PREV ] record
[ constant ]
[ OF table ]
[ WHERE expression ]
[ USE-INDEX index ]
[ USING [ FRAME frame ] field
  [ AND [ FRAME frame ] field ] ... ]
[ SHARE-LOCK | EXCLUSIVE-LOCK | NO-LOCK ]
[ NO-WAIT ]
[ NO-PREFETCH ]
[ NO-ERROR ]

You can specify the OF, WHERE, USE-INDEX, and USING options in any order.

FIND CURRENT record
[ SHARE-LOCK | EXCLUSIVE-LOCK | NO-LOCK ]
[ NO-WAIT ]
[ NO-PREFETCH ]
[ NO-ERROR ]

FIRST

Finds the first record in the table that meets the characteristics you might have specified with record. If the buffer named in the record was preselected in a DO or REPEAT statement, FIND locates the first record in that preselected subset of records.

LAST

Finds the last record in the table that meets the specified characteristics of the record. If the buffer named in the record was preselected in a DO or REPEAT statement, FIND locates the last record in that preselected subset of records.

NEXT

Finds the next record in the table that meets the specified characteristics of the record. If no record has been found, the buffer contents specified by record are unknown, with a ROWID equal to the Unknown value (?). If the buffer named in the record was preselected in a DO or REPEAT statement, FIND locates the next record in that preselected subset of records.
PREV

Finds the previous record in the table. If no record has been found, the buffer contents specified by record are unknown, with a ROWID equal to the Unknown value (?). If the buffer named in the record was preselected in a DO or REPEAT statement, FIND locates the previous record in that preselected subset of records.

CURRENT

Refetches the current record in the buffer with the specified lock status.

record

Identifies the record you want to retrieve. The record parameter can be a reference to a database table or a defined buffer.

constant

The value of a single component, unique, primary index for the record you want.

```ABL
FIND Customer 1.
```

ABL converts this FIND statement with the constant option of 1.

```ABL
```

The CustNum field is the only component of the primary index of the Customer table. If you use the constant option, you must use it once in a single Record phrase, and it must precede any other options in the Record phrase.

OF table

Qualifies the records by relating the record to a record in another table.

```ABL
PROMPT-FOR Order.OrderNum.
FIND Order USING OrderNum.
DISPLAY Order.
FIND Customer OF Order.
DISPLAY Customer.
```

The OF option relates the order table to the Customer table, telling the AVM to select the Customer record related to the Order record currently being used. When you use OF, all fields participate in match criteria, if an index is multi-field. The relationship is based on having a UNIQUE index in one table. ABL converts the FIND statement with the OF option to the following:

```ABL
```

You can access related tables using WHERE, whether or not the field names of the field or fields that relate the tables have the same name.
WHERE expression

Qualifies the records you want to access. The expression is a constant, field name, variable name, or expression whose value you want to use to select records. You can use the WHERE keyword even if you do not supply an expression.

```
FOR EACH Customer WHERE {*}
```

The WHERE clause may not work the same way against a DataServer as it does against the OpenEdge database. Refer to the appropriate DataServer Guide (OpenEdge Data Management: DataServer for ODBC or OpenEdge Data Management: DataServer for Oracle) for additional information on how this feature will perform.

**Note:** You cannot reference a BLOB or CLOB field in a WHERE clause.

USE-INDEX index

Identifies the index you want to use while selecting records. If you do not use this option, the AVM selects an index to use based on the criteria specified with the WHERE, USING, OF, or constant options.

```
```

One or more names of fields for selecting records. The field you name in this option must have been entered previously, usually with a PROMPT-FOR statement. The field must be viewed as a fill-in or text widget.

The USING option translates into an equivalent WHERE option.

```
PROMPT-FOR Customer.CustNum.
FIND Customer USING Customer.CustNum.
```

This FIND statement is the same as the following statement:

```
```

The CustNum field is a non-abbreviated index. However, consider this example:

```
PROMPT-FOR Customer.Name.
FIND Customer USING Customer.CustName.
```

If the name field is an abbreviated index of the Customer table, ABL converts the FIND statement with the USING option into this following statement:

```
FIND Customer WHERE Customer.Name BEGINS INPUT Customer.Name.
```

Note that field can be expanded to be FRAME frame field.
SHARE-LOCK

Tells the AVM to put a SHARE-LOCK on records as they are read. Other users can still read a record that is share locked, but they cannot update it. By default, the AVM puts a SHARE-LOCK on a record when it is read, and automatically puts an EXCLUSIVE-LOCK on a record when it is modified (unless the record is already EXCLUSIVE-LOCKed).

If you use the SHARE-LOCK option and the AVM tries to read a record that is EXCLUSIVE-LOCKed by another user, the AVM waits to read the record until the EXCLUSIVE-LOCK is released. The AVM displays a message to the user of that procedure, identifying the table that is in use, the user ID of the user, and the tty of the terminal using the table.

If you are using a record from a work table, the AVM disregards the SHARE-LOCK option.

EXCLUSIVE-LOCK

Tells the AVM to put an EXCLUSIVE-LOCK on records as they are read. Other users cannot read or update a record that is EXCLUSIVE-LOCKed, except by using the NO-LOCK option. They can access that record only when the EXCLUSIVE-LOCK is released. The AVM automatically puts a SHARE-LOCK on a record when it is read and automatically puts an EXCLUSIVE-LOCK on a record when it is updated.

If a record is read specifying EXCLUSIVE-LOCK, or if a lock is automatically changed to EXCLUSIVE-LOCK by an update, a user’s read or update will wait if any other user has the record SHARE-LOCKed or EXCLUSIVE-LOCKed.

When a procedure tries to use a record that is EXCLUSIVE-LOCKed by another user, the AVM displays a message identifying the table that is in use, the user ID of the user, and the tty of the terminal using the table.

If you are using a record from a work table, the AVM disregards the EXCLUSIVE-LOCK option.

NO-LOCK

Tells the AVM to put no locks on records as they are read, and to read a record even if another user has it EXCLUSIVE-LOCKed.

Other users can read and update a record that is not locked. By default, the AVM puts a SHARE-LOCK on a record when it is read (unless it is using a CAN-FIND function, which defaults to NO-LOCK), and automatically puts an EXCLUSIVE-LOCK on a record when it is updated (unless the record is already EXCLUSIVE-LOCKed). A record that has been read NO-LOCK must be reread before it can be updated, as shown in this example:

```
DEFINE VARIABLE rid AS ROWID NO-UNDO.
FIND FIRST Customer NO-LOCK.
    rid = ROWID(Customer).
FIND Customer WHERE ROWID(Customer) = rid EXCLUSIVE-LOCK.
```
If a procedure finds a record and it places it in a buffer using NO-LOCK and you then re-find that record using NO-LOCK, the AVM does not reread the record. Instead, it uses the copy of the record that is already stored in the buffer.

When you read records with NO-LOCK, you have no guarantee of the overall consistency of those records because another user might be in the process of changing them. For example, when a record is updated, changes to indexed fields are written immediately, but changes to other fields are deferred. In the meantime, the record is in an inconsistent state. For example, the following procedure might display a \texttt{CustNum} of 0 if another user’s active transaction has created a record and assigned a value to the indexed field \texttt{CustNum} that is greater than 100:

\begin{verbatim}
FOR EACH Customer WHERE Customer.CustNum > 100 NO-LOCK:
    DISPLAY Customer.CustNum.
END.
\end{verbatim}

If you are using a record from a work table, the AVM disregards the NO-LOCK option.

\textbf{NO-WAIT}

Causes FIND to return immediately and raise an error condition if the record is locked by another user (unless you use the NO-ERROR option on the same FIND statement). For example:

\begin{verbatim}
FIND Customer USING cust-name NO-ERROR NO-WAIT.
\end{verbatim}

Without the NO-WAIT option, the AVM waits until the record is available.

The AVM ignores NO-WAIT when it is used with work tables and databases that are only accessed by a single user.

\textbf{NO-PREFETCH}

Specifies that only one record is sent across the network at a time. If you are accessing a remote server and do not specify this option, the AVM might send more than one record from the server to the client in each network packet. Sending more than one packet may, in rare cases, create inconsistencies with Progress Version 6 or earlier.

\textbf{NO-ERROR}

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the \texttt{ERROR-STATUS} system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

For the FIND statement with NO-ERROR, you can use the \texttt{AVAILABLE} function to test if FIND found a record.

To check for errors after a statement that uses the NO-ERROR option:
• Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

• Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

• Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

• NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

• A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

• When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

• If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Examples**

This procedure produces a report that shows all the customers who bought a particular item, and the quantity that they bought. The procedure finds an item record, the order-lines that use that item, the order associated with each order-line, and the customer associated with each order.
The FIND FIRST statement in the following procedure finds the first record with a name field value that alphabetically follows the name supplied by the user. The FIND NEXT statement uses the name index to find the next record in the table, using the name index.

```
r-find.p

REPEAT:
  PROMPT-FOR Item.ItemNum.
  FIND Item USING Item.ItemNum.
  DISPLAY Item.ItemNum Item.ItemName.
REPEAT:
  FIND NEXT OrderLine OF Item.
  FIND Order OF OrderLine.
END.
END.
```

The FIND statement, the AVM selects an index to use based on the WHERE condition or the USE-INDEX option.

```
r-find2.p

DEFINE VARIABLE start-name NO-UNDO LIKE Customer.Name.
REPEAT:
  SET start-name.
  FIND FIRST Customer WHERE Customer.Name >= start-name.
REPEAT:
  DISPLAY Customer.Name.
  FIND NEXT Customer USE-INDEX name.
END.
END.
```

Notes

- If a FIND statement fails, it indicates that the buffer named in record contains no record.
- If the AVM finds an old record in the record buffer when executing a FIND, it validates the record then writes it out. (If the record fails validation, the AVM returns an error message.) Then it clears the buffer and stores the located record in the record buffer.
- A FIND statement that does not supply FIRST, LAST, NEXT, or PREV is a unique FIND and must be able to locate, at most, one record based solely on the conditions in the expression or WHERE clause it is using.
- Fields referenced in the WHERE clause do not have to be indexed.
- WHERE conditions can include Boolean operations.
- If a FIND NEXT or FIND PREV does not find another record, the AVM takes the end-key action. By default, this action is UNDO, LEAVE for a FOR EACH, REPEAT, or procedure block.
- See the DEFINE BUFFER statement reference entry for a description of how to use FIND on a PRESELECTed set of records.
- When you use the FIND statement, the AVM selects an index to use based on the WHERE condition or the USE-INDEX option.
- Your position in an index is established when you find a record and is only modified by subsequent record retrievals, not by CREATEs or by changing indexed field values. After a failed FIND, you cannot be certain of the cursor position.
• If you are using the FIND statement to find a record in a work table, you must use the FIRST, LAST, NEXT, or PREV option with the FIND statement.

• In a REPEAT block, if you use the FIND NEXT statement to find a record and then do an UNDO, RETRY of a block, the FIND NEXT statement reads the next record in the table, rather than the one found in the block iteration where the error occurred:

```
REPEAT:
  FIND NEXT Order.
  DISPLAY Order.
  SET Order.OrderNum.
  SET Order.OrderDate Order.PromiseDate.
END.
```

The AVM does an UNDO, RETRY if there is an error and you explicitly use the UNDO, RETRY statement, or if you press END-ERROR on the second or later windows interaction in a block.

Here, if you press END-ERROR during the second SET statement, the AVM displays the next record in the table.

If you are using a FOR EACH block to read records, and do an UNDO, RETRY during the block, you see the same record again rather than the next record.

If you want to use a REPEAT block and want to see the same record in the event of an error, use the RETRY function:

```
REPEAT:
  IF NOT RETRY THEN FIND NEXT Order.
  DISPLAY Order.
  SET Order.OrderNum.
  SET Order.OrderDate Order.PromiseDate.
END.
```

• When you use FIND NEXT or FIND PREV to find a record after updating another record, be careful not to lose your updates in case the record you want to find is unavailable.

```
FIND FIRST Customer.
REPEAT:
  UPDATE Customer.
  FIND NEXT Customer.
END.
```

In this example, if the FIND NEXT statement fails to find the customer record, any changes made during the UPDATE statement are undone. To avoid this, use the following technique:

```
FIND FIRST Customer.
REPEAT:
  UPDATE Customer.
  FIND NEXT Customer NO-ERROR.
  IF NOT AVAILABLE Customer THEN LEAVE.
  END.
```

After you use the FIND LAST statement to find the last record in a table, the AVM positions the index cursor on that record. Any references within the same record scope to the next record fail. For example:

```plaintext
FIND LAST Customer.
RELEASE Customer.
DISPLAY AVAILABLE Customer.
REPEAT:
    FIND NEXT Customer.
    DISPLAY Customer.Name.
END.
```

In this example, the RELEASE statement releases the last Customer record from the Customer record buffer and the following DISPLAY statement displays FALSE because the Customer record is no longer available. However, the index cursor is still positioned on that last record. Therefore, the FIND NEXT statement fails.

If you use FIND . . . WHERE ROWID rowid = . . . on a PRESELECTed list of records, the temporary preselect index cursor is not reset. So, FIND NEXT does not find the record that follows record rowid in the preselected list. (See the DO statement and REPEAT statement reference entries for details.)

When you use a FIND NEXT or FIND PREV statement in a subprocedure to access a record from a shared buffer, remember the following:

- When you run an ABL procedure, the AVM creates a cursor indicator for each index accessed through a FIND statement in the procedure and each NEW buffer defined in the procedure. A cursor indicator serves as an anchor for index cursors associated with a table or buffer. An index cursor is attached to the cursor indicator when you enter a block of code where a record buffer is scoped. If two different indexes are used for the same record buffer within a single block of code, two index cursors are attached to the same cursor indicator. When the program control leaves the block where a record buffer is scoped, all index cursors attached to the cursor indicator are released.

- When the AVM encounters a subprocedure in a procedure, it constant, field name, variable name, or checks through the existing index cursors before creating any other index cursors required by the statements in the subprocedure.

- If the USE-INDEX of the FIND NEXT or FIND PREV statement in a subprocedure accesses an index cursor for a shared buffer that existed prior to the beginning of the subprocedure, the FIND NEXT or FIND PREV statement returns the next or previous record for the shared buffer, based upon the last record found in that buffer and the USE-INDEX of the FIND statement.

- If the USE-INDEX of the FIND NEXT or FIND PREV statement in a subprocedure accesses an index cursor created for a shared buffer at the beginning of the subprocedure, the FIND NEXT or FIND PREV statement returns the first or last record for the shared buffer, based upon the USE-INDEX of the FIND statement.

If a field or variable referenced with FIND is used in more than one frame, then the AVM uses the value in the frame most recently introduced in the procedure. To make sure you are using the appropriate frame, use the FRAME option with the FIND function to reference a particular frame.
FIRST function

- When a FIND statement executes, any FIND trigger defined for the table is executed.
- The FIND CURRENT statement is useful for maintaining small transaction size in updates. For an example, see the CURRENT-CHANGED function reference entry.
- FIND triggers do not execute for a FIND CURRENT statement.
- ABL does not allow a FIND statement within a FOR EACH block unless you specify a different table than the one referenced in the FOR EACH block. When you attempt to compile the following example, ABL returns the error message “FIND cannot be processed for a FOR EACH mode record”:

  ```abl
  FOR EACH Customer NO-LOCK:
    FIND CURRENT Customer.
  END.
  ```

- ABL restricts the FIND statement within a PRESELECT block in the following situations:
  - You cannot specify a lock option on the FIND statement. You must specify it in the PRESELECT phrase. Attempting to compile the following example produces the error message “LOCK keyword illegal on FIND within a PRESELECT for the same table”:

  ```abl
  DO PRESELECT EACH Customer:
    FIND NEXT Customer NO-LOCK.
  END.
  ```

  - You cannot specify a unique FIND or a FIND CURRENT for the same table. The following example produces the error message “Unique FIND not allowed within a PRESELECT on the same table” when you try to compile it:

  ```abl
  DO PRESELECT EACH Customer:
    FIND Customer 5.
  END.
  ```

FIRST function

Returns a TRUE value if the current iteration of a DO, FOR EACH, or REPEAT . . . BREAK block is the first iteration of that block.

Syntax

FIRST ( break-group )
**break-group**

The name of a field or expression you name in the block header with the BREAK BY option.

**Example**

The `r-first.p` procedure displays the order number, OrderLines on the Order, the extended price of each OrderLine, and a total order value for each Order record:

```r-first.p
DEFINE VARIABLE order-value AS DECIMAL NO-UNDO LABEL "Order-value".
FOR EACH Order NO-LOCK:
  DISPLAY Order.OrderNum.
  FOR EACH OrderLine OF Order BREAK BY OrderLine.Qty * OrderLine.Price:
    IF FIRST(OrderLine.Qty * OrderLine.Price) THEN
      order-value = 0.
    END.
  END.
  DISPLAY order-value.
END.
```

Because the inner FOR EACH block iterates until the AVM reads all the order-lines, the procedure must set the order-value variable to 0 each time a new order is used in that block. The FIRST function uses the `(qty * price)` expression as the `break-group` to keep track of whether or not the current iteration is the first iteration of the FOR EACH block.

**See also**

DO statement, FIRST-OF function, FOR statement, LAST function, LAST-OF function, REPEAT statement

---

**FIRST-OF function**

Returns a TRUE value if the current iteration of a DO, FOR EACH, or REPEAT . . . BREAK block is the first iteration for a new break group, and modifies all three block types.

**Syntax**

```
FIRST-OF ( break-group )
```

**Example**

This procedure generates a report that lists all the item records grouped by catalog page. When the `CatPage` value changes, the procedure clears the current list of items and displays items belonging to the new catalog page. The FIRST-OF function uses the value of the `CatPage` field to determine when that value is different from the value during the last iteration.
Note
When you calculate in a block use the BREAK option to tell the AVM to calculate when the value of certain expressions changes. The AVM uses default formatting to display the results of these calculations. To control the formatting, use the FIRST-OF function to determine the start of a break group and then change the formatting.

See also
DO statement, FIRST function, FOR statement, LAST function, LAST-OF function, REPEAT statement

FIX-CODEPAGE statement
Sets the code page of an empty LONGCHAR variable. When set to a valid code page, the code page of the specified variable is fixed and overrides any default behavior in assignment operations (including the COPY-LOB, OVERLAY, and SUBSTRING statements).

Syntax
```
FIX-CODEPAGE (longchar) = codepage
```

*longchar*

The name of a LONGCHAR variable. The variable must be set to the Unknown value (?) or the empty string (""). If the string length is greater than 0, the AVM returns an error.

*codepage*

A character expression that evaluates to the name of a code page. The name you specify must be a valid code page name available in DLC/convmap.cp. If codepage is the Unknown value (?), the code page of the LONGCHAR variable is not fixed.

See also
GET-CODEPAGE function, IS-CODEPAGE-FIXED function

FOR statement
Starts an iterating block that reads a record from each of one or more tables at the start of each block iteration. Use an END statement to end a FOR block.

Data movement

```
Database ➔ Record buffer ➔ Screen buffer
```
Block properties

Iteration, record reading, record scoping, frame scoping, transactions by default.

Syntax

```
[ label: ]
FOR [ EACH | FIRST | LAST ] record-phrase
[ , [ EACH | FIRST | LAST ] record-phrase ] ...
[ query-tuning-phrase ]
[ BREAK ]
[ BY expression [ DESCENDING ]
| COLLATE ( string , strength [ , collation ] ) [ DESCENDING ] ] ...
[ variable = expression1 TO expression2 [ BY k ] ]
[ WHILE expression ]
[ TRANSACTION ]
[ STOP-AFTER expression ]
[ on-error-phrase ]
[ on-endkey-phrase ]
[ on-quit-phrase ]
[ on-stop-phrase ]
[ frame-phrase ] :
for-body
```

**EACH**

Starts an iterating block, finding a single record on each iteration. If you do not use the EACH keyword, the Record phrase you use must identify exactly one record in the table.

**FIRST**

Uses the criteria in the record-phrase to find the first record in the table that meets that criteria. The AVM finds the first record before any sorting.

The following statement displays Customer 1 (CustNum is the primary index of the Customer table), not the Customer with the lowest CreditLimit:

```
FOR FIRST Customer NO-LOCK BY Customer.CreditLimit:
  DISPLAY Customer.
END.
```

The following statement displays the Customer with the lowest CreditLimit:
FOR EACH Customer NO-LOCK BY Customer.CreditLimit:
    DISPLAY Customer.
    LEAVE.
END.

See the Notes section for more information on using this option.

LAST

Uses the criteria in the record-phrase to find the last record in the table that meets that criteria. The AVM finds the last record before sorting.

FOR LAST Customer BY Customer.CreditLimit:
    DISPLAY Customer.
END.

The procedure above displays the Customer with the highest Customer number (CustNum is the primary index of the Customer table), not the Customer with the highest CreditLimit.

A procedure that displays the Customer with the highest CreditLimit looks like the following:

FOR EACH Customer NO-LOCK BY Customer.CreditLimit DESCENDING:
    DISPLAY Customer.
    LEAVE.
END.

See the Notes section for more information on using this option.

record-phrase

Identifies the set of records you want to retrieve. This can also be the built-in buffer name, proc-text-buffer, that you can use to return table rows from a stored procedure.

To use FOR EACH/FIRST/LAST to access a record in a table defined for multiple databases, you must qualify the record’s table name with the database name.

This is the syntax for record-phrase:

Syntax

\[
\text{record} \quad [\text{constant}] \quad [\text{OF table}] \quad [\text{USE-INDEX index}] \quad [\text{USING [ FRAME field ] field [ AND [ FRAME field ] field ] ...}] \quad [\text{WHERE expression}] \quad [\text{SHARE-LOCK | EXCLUSIVE-LOCK | NO-LOCK}] \quad [\text{NO-PREFETCH}]
\]
Specifying multiple occurrences of `record-phrase` selects the tables using an inner join.

For more information on `record-phrase` and inner joins, see the Record phrase reference entry.

`query-tuning-phrase`  
Allows programmatic control over the execution of a DataServer query. Following is the syntax for the `query-tuning-phrase`:

**Syntax**

```plaintext
QUERY-TUNING
{
  [   LOOKAHEAD [ CACHE-SIZE integer ] ]
  | NO-LOOKAHEAD
  ]
  [   DEBUG { SQL | EXTENDED } | NO-DEBUG ]
  [   SEPARATE-CONNECTION | NO-SEPARATE-CONNECTION ]
  [   JOIN-BY-SQLDB | NO-JOIN-BY-SQLDB ]
  [   BIND-WHERE | NO-BIND-WHERE ]
  [   INDEX-HINT | NO-INDEX-HINT ]
}
)
```

For more information on the `query-tuning-phrase`, refer to the appropriate DataServer Guide (OpenEdge Data Management: DataServer for ODBC, OpenEdge Data Management: DataServer for Oracle, or OpenEdge Data Management: DataServer for Microsoft SQL Server).

**BREAK**

Over a series of block iterations, you might want to do some work based on whether the value of a certain field changes. This field defines a break group. For example, you might be accumulating some value, such as a total. You use the BREAK option to define `State` as the break group. For example:

```plaintext
FOR EACH Customer BREAK BY Customer.State:
  DISPLAY Customer.State Customer.Name
  Customer.CreditLimit (TOTAL BY state).
END.
```

Here, the AVM accumulates the total `CreditLimit` for all the customers in the `Customer` table. Each time the value of the `State` field changes, the AVM displays a subtotal of the `CreditLimit` values for customers in that state.

You can use the BREAK option anywhere in the block header, but you must also use the BY option to name a sort field.

You can use the BREAK option in conjunction with the ACCUMULATE statement and ACCUM function. For more information, see the reference entries for those language elements.
FOR statement

**BY expression [ DESCENDING ]**

Sorts the selected records by the value of expression. If you do not use the BY option, the AVM retrieves records in the order of the index used to satisfy the record-phrase criteria, or the primary index if no criteria is given. The DESCENDING option sorts the records in descending order (not in the default ascending order).

**Note:** You cannot reference a BLOB or CLOB field in the BY option.

You can use multiple BY options to do multi-level sorting. For example:

```
FOR EACH Customer BY Customer.CreditLimit BY Customer.Name
```

Here, the Customers are sorted in order by CreditLimit. Within each CreditLimit value, Customers are sorted alphabetically by Name.

There is a performance benefit if an index on expression exists: BREAK BY does not have to perform the sort that is otherwise required to evaluate FIRST, LAST, FIRST-OF, and LAST-OF expressions.

**COLLATE (string, strength [, collation] ) [ DESCENDING ]**

Generates the collation value of a string after applying a particular strength, and optionally, a particular collation. The DESCENDING option sorts the records in descending order (not in default ascending order).

- **string**
  A CHARACTER expression that evaluates to the string whose collation value you want to generate.

- **strength**
  A CHARACTER expression that evaluates to an ABL comparison strength or an International Components for Unicode (ICU) comparison strength.

The ABL comparison strengths include:

- **RAW** — Generates a collation value for the string based on its binary value.
- **CASE-SENSITIVE** — Generates a case-sensitive collation value for the string based on a particular collation. If you specify this strength with an ICU collation, the AVM applies the ICU TERTIARY strength.
- **CASE-INSENSITIVE** — Generates a case-insensitive collation value for the string based on a particular collation. If you specify this strength with an ICU collation, the AVM applies the ICU SECONDARY strength.
- **CAPS** — Generates a collation value for the string based on its binary value after converting any lowercase letters in the string to uppercase letters, based on the settings of the Internal Code Page (-cpinternal) and Case Table (-cpcase) startup parameters.
The ICU comparison strengths include:

- **PRIMARY** — Generates a collation value for the base characters in the string.
- **SECONDARY** — Generates a collation value for the base characters and any diacritical marks in the string.
- **TERTIARY** — Generates a case-sensitive collation value for the base characters and any diacritical marks in the string.
- **QUATERNARY** — Generates a case-sensitive collation value for the base characters and any diacritical marks in the string, and distinguishes words with and without punctuation. ICU uses this strength to distinguish between Hiragana and Katakana when applied with the ICU-JA (Japanese) collation. Otherwise, it is the same as TERTIARY.

**Note:** Use ICU comparison strengths only with ICU collations.

**collation**

A CHARACTER expression that evaluates to the name of an ABL collation table or ICU collation. If `collation` does not appear, COLLATE uses the collation table of the client.

The AVM reports an error and stops execution if one of the following occurs:

- `strength` does not evaluate to a valid value.
- `collation` does not evaluate to a collation table residing in the `convmap.cp` file.
- `collation` evaluates to a collation table that is not defined for the code page corresponding to the `-cpinternal` startup parameter.

**variable = expression1 TO expression2 [ BY k ]**

Identifies the name of a field or variable whose value you are incrementing in a loop. The `expression1` is the starting value for `variable` on the first iteration of the loop. The `k` is the amount to add to `variable` after each iteration and must be a constant. It \((k)\) defaults to 1. The `variable`, `expression1`, and `expression2` parameters must be integers.

When `variable` exceeds `expression2` (or is less than `expression2` if `k` is negative) the loop ends. Since `expression1` is compared to `expression2` at the start of the first iteration of the block, the block can be executed 0 times. The AVM re-evaluates `expression2` on each iteration of the block.

**WHILE expression**

Indicates the condition in which you want the FOR EACH block to continue processing the statements within it. Using the `WHILE expression` option causes the block to iterate as long as the condition specified by the expression is TRUE or the AVM reaches the end of the index it is scanning, whichever comes first. The expression is any combination of constants, operators, field names, and variable names that yield a logical value.
TRANSACTION

Identifies the FOR EACH block as a system transaction block. The AVM starts a system transaction for each iteration of a transaction block if there is not already an active system transaction. See *OpenEdge Getting Started: ABL Essentials* for more information on transactions.

STOP-AFTER expression

The STOP-AFTER phrase specifies a time-out value for a DO, FOR, or REPEAT block. The integer expression specifies the number of seconds each iteration of a block has until a time-out occurs. If a time-out occurs, the AVM raises the STOP condition and default STOP condition handling occurs. Use an ON STOP phrase on the block (or an enclosing block) to alter the default STOP condition handling.

If the block iteration completes before the specified time expires, the timer resets to expression for the next iteration. In other words, the timer is limited to the scope of a single block iteration. If a block with a STOP-AFTER phrase encloses another block or calls another block, the timer continues while the inner blocks execute.

If a block with a STOP-AFTER phrase contains a nested block with a STOP-AFTER phrase, then each has a timer in effect. If the outer block timer expires while the inner block is executing, the STOP condition is raised even if the timer for the inner block has not expired.

If the STOP condition is handled and execution resumes within the scope of a block with a STOP-AFTER phrase, no timer is in effect until the next iteration of a block with a STOP-AFTER phrase. In other words, all old timers are dismissed but new timers can now be established.

When the timer expires, the STOP condition is raised on the current statement.

Two important use cases for the STOP-AFTER phrase are to time-limit dynamic queries and to time-limit a procedure call. The following example time-limits a procedure call using a RUN statement:

```
DEFINE VARIABLE cnt as INTEGER INITIAL 0.
PROCEDURE bumpCnt:
  cnt = cnt + 1.
END.

DO STOP-AFTER 5:
  RUN bumpCnt.
END.
```

Use this technique to also make timed calls to class methods and user-defined functions.

The following example is simplified code that lets you try different STOP-AFTER cases.
DEFINE VARIABLE EndlessCount AS INTEGER INITIAL 0.

DO STOP-AFTER 5 ON STOP UNDO, LEAVE:

    FOR EACH Customer STOP-AFTER 1:
        ASSIGN EndlessCount = EndlessCount + 1.
/* Try a complex operation on a Customer record to use up the timer in a single iteration and raise the STOP condition in the inner block */
        END.

    MESSAGE "Procedure half complete. Endlesscount = " EndlessCount ".".

    REPEAT STOP-AFTER 1:
        ASSIGN EndlessCount = EndlessCount + 1.
/*IF EndlessCount > 2000 THEN LEAVE. */
        END.

    MESSAGE "Procedure nearly complete. Endlesscount = " EndlessCount ".".

END.

MESSAGE "Procedure complete. Endlesscount = " EndlessCount ".".

If you run this code as is, the outer DO block establishes a 5 second time limit for the work of the DO block and all inner blocks. When the inner FOR EACH block starts, another timer is established for the first iteration of this block. When the first FOR EACH iteration completes, its timer is reset to 1 second for the next iteration. Meanwhile, the outer timer on the DO block continues without interruption.

The FOR EACH block completes and execution continues forward to the REPEAT block, which is an endless loop. The REPEAT block also has a 1 second timer for each iteration of the block. At some point, the outer 5 second timer elapses and the AVM raises the STOP condition. The STOP condition is raised on the statement the AVM was executing when the timer elapsed. Normal STOP handling proceeds from that point.

As the stack unwinds during STOP processing, the AVM encounters the ON STOP phrase on the DO block. The ON STOP phrase dismisses the STOP condition and resumes normal execution with the next statement following the DO block, as directed by the LEAVE option.

If you remove the comments from the IF statement in the REPEAT block, the block will complete within the outer time limit and the STOP condition is not raised.

If you want to experiment with elapsed timers on an inner block, insert a complex operation inside the FOR EACH block.

In the following example, the STOP-AFTER expression is modified during program execution:
Because the STOP-AFTER expression is re-evaluated for each iteration of a looping block, any changes made to the expression during the iteration effect the timer for the block. In the example, the STOP-AFTER time limit is specified by the variable \textit{stopTime}, which is initially set to 30 seconds. The procedure contains an iterating block which runs a procedure that executes for 10 seconds.

On the first iteration of the \textbf{DO WHILE TRUE} loop, \textit{stopTime} is 30 seconds. The loop executes for 10 seconds, and then divides \textit{stopTime} by 2. On the second iteration, the \textit{stopTime} is 15 seconds; again the loop executes for 10 seconds, and then divides \textit{stopTime} by 2. On the third iteration, the \textit{stopTime} is 8 seconds. This time, the procedure \texttt{spinHere} runs for 8 seconds and then raises \texttt{STOP}. The \texttt{STOP} condition is handled by the \textbf{DO} block, and then the program displays the message \texttt{program finished}.

If a code block is called with a time limit of zero, the block is executed as if the STOP-AFTER phrase was omitted from the block declaration.

Consider the following example:

```
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE stopTime AS INTEGER NO-UNDO INITIAL 30.

DO WHILE TRUE STOP-AFTER stopTime ON STOP UNDO, LEAVE:
    RUN spinHere (10000).
    stopTime = stopTime / 2.
END.
MESSAGE "program finished".

PROCEDURE spinHere:
    DEFINE INPUT PARAMETER spinLimit AS INT64 NO-UNDO.

    DEFINE VARIABLE endTime AS INT64 NO-UNDO.
    DEFINE VARIABLE loopFlag AS LOGICAL NO-UNDO.

    ASSIGN
        loopFlag = TRUE
        endTime = ETIME(FALSE) + spinLimit.

    DO WHILE loopFlag:
        IF (ETIME(FALSE) > endTime) THEN
            loopFlag = FALSE.
        END.
    END.
END PROCEDURE.
```
In this example, procedure foo is run from within a timed block with a 10 second time limit; procedure bar is called from within the timed block, and contains an iterating block that specifies the STOP-AFTER phrase. Because the value of the STOP-AFTER expression evaluates to zero (that is, the current value of the barLimit variable), the block within bar is executed as an untimed block. However, the rules for execution of an untimed block within a timed block apply, so the untimed block in bar is executed with an implicit iteration time limit of 10 seconds.

Other points to consider are:

- If the expression evaluates to zero or less, then this is the equivalent of not specifying a STOP-AFTER phrase.
- STOP-AFTER phrases are not intended to interact with user interfaces.
- Blocking calls to third party software components, where the AVM has transferred execution control, cannot be timed out. This category includes operating system calls, MS Windows system calls, and calls to any third party DLLs and Unix shared objects.

\textit{on-error-phrase}

Describes the processing that takes place when there is an error during a block. This is the syntax for the ON ERROR phrase:

\textbf{Syntax}

\begin{verbatim}
ON ERROR UNDO
  [ label1 ]
  [ , LEAVE [ label2 ] ]
  [ , NEXT [ label2 ] ]
  [ , RETRY [ label1 ] ]
  [ , RETURN [ return-value ]
    ERROR [ return-value | error-object-expression ] |
    NO-APPLY ]
  [ , THROW ]
\end{verbatim}
FOR statement

For more information, see the ON ERROR phrase reference entry.

on-endkey-phrase

Describes the processing that takes place when the ENDKEY condition occurs during a block. This is the syntax for the ON ENDKEY phrase:

Syntax

```
ON ENDKEY UNDO
  [ label1 ]
  [ , LEAVE [ label2 ]
  | , NEXT [ label2 ]
  | , RETRY [ label1 ]
  | , RETURN [ return-value ]
    ERROR [ return-value | error-object-expression ] | NO-APPLY ]
```

For more information, see the ON ENDKEY phrase reference entry.

on-quit-phrase

Describes the processing that takes place when a QUIT statement is executed during a block. This is the syntax for the ON QUIT phrase:

Syntax

```
ON QUIT
  [ UNDO [ label1 ] ]
  [ , LEAVE [ label2 ]
  | , NEXT [ label2 ]
  | , RETRY [ label1 ]
  | , RETURN [ return-value ]
    ERROR [ return-value | error-object-expression ] | NO-APPLY ]
```

For more information, see the ON QUIT phrase reference entry.

on-stop-phrase

Describes the processing that takes place when the STOP conditions occurs during a block. This is the syntax for the ON STOP phrase:
FOR statement

Syntax

```
ON STOP UNDO
  [ label1 ]
  [ , LEAVE [ label2 ]
  | , NEXT [ label2 ]
  | , RETRY [ label1 ]
  | , RETURN [ return-value ]
    ERROR [ return-value | error-object-expression ] | NO-APPLY ]
```

For more information, see the ON STOP phrase reference entry.

frame-phrase

Specifies the overall layout and processing properties of a frame. For more information on frame-phrase, see the Frame phrase reference entry.

for-body

The body of the FOR block. Define for-body using the following syntax:

```
for-logic
  .
  .
  [ catch-block [ catch-block ... ] ]
  [ finally-block ]
END .
```

for-logic

The logic of the FOR block. This logic can contain the ABL statements allowed within the routine-level block (e.g., procedure, user-defined, or method) where the FOR statement is defined.

Each logic statement must end with a period.

catch-block

Specifies a CATCH statement that defines error handling code for one or more error types. For more information on catch-block, see the CATCH statement reference entry.

finally-block

Specifies a FINALLY statement that defines the processing that must occur after all other processing in the block occurs. For more information on finally-block, see the FINALLY statement reference entry.

END

Specifies the end of the FOR block definition. You must end the FOR block definition with the END statement.
**Examples**

This procedure reads Customer records that have a `CustNum` less than 12, sorting the records in order by `State` before displaying them:

```
r-fore.p
FOR EACH Customer NO-LOCK WHERE Customer.CustNum < 12 BY Customer.State:
END.
```

The next procedure gets information from four related tables (Customer, Order, OrderLine, and Item) and displays some information from each. Before displaying the information, the FOR EACH statement sorts it in order by the `PromiseDate` field, then, within that field, in order by `CustNum`. Within the `CustNum` field, the data is sorted by the `LineNum` field.

```
r-fore2.p
FOR EACH Customer NO-LOCK, EACH Order OF Customer NO-LOCK,
    EACH OrderLine OF Order NO-LOCK, Item OF OrderLine NO-LOCK
    BY Order.PromiseDate BY Customer.CustNum BY OrderLine.LineNum:
    DISPLAY Order.PromiseDate Customer.CustNum Order.OrderNum
    OrderLine.LineNum Item.ItemNum Item.ItemName.
END.
```

This procedure uses the LAST option to display information on the last Order of each Customer:

```
r-fore3.p
FOR EACH Customer NO-LOCK, LAST Order OF Customer:
    DISPLAY Customer.CustNum Customer.Name Order.OrderNum Order.OrderDate
    Order.Instructions.
    PAUSE 1 NO-MESSAGE.
    Order.Instructions = "Last order".
    DISPLAY Order.Instruction.
END.
```

**Notes**

- At compile time, ABL determines which index or indexes to use for retrieving records from a table, based on the conditions in the Record phrase. For compatibility with Progress Version 6 or earlier, you can force ABL to use only one index by specifying the USE-INDEX option or by using the Version 6 Query (-v6q) parameter.

- If you specify the `-v6q` startup parameter, an index component is involved in an equality match if it is used in the Record phrase conditions in the following form:

```
Syntax

field = expression
```

Where the `expression` is independent of any fields in the table that the index is being selected from. A condition involving OF and USING are equivalent to this form. A field is involved in a range match if it is used in a condition of this form:

```
Syntax

field [ < | <= | > | >= | BEGINS ] expression
```
The BEGINS operator translates into two range matches for a field.

An equality or range match is considered active if the equality or range condition stands on its own or is related to other conditions solely through the AND operator (for example, not through OR or NOT).

A field is involved in a sort match if it is used in a BY option of this form:

**Syntax**

```
BY field [ DESCENDING ]
```

- If you specify the -v6q startup parameter, the following list describes the rules the OpenEdge database manager uses to choose an index for an OpenEdge database:
  - If you specify the record by ROWID, the AVM accesses the record directly without using an index.
  - If you use the USE-INDEX option, in the record-phrase, the AVM uses the index you name in that option.
  - For each index in the table, the ABL compiler looks at each index component in turn and counts the number of active equality, range, and sort matches. ABL ignores the counts for any components of an index that occur after a component that has no active equality match. ABL compares the results of this count and selects the best index. ABL uses the following order to determine the better of any two indexes:
    1. If one index is unique and all of its components are involved in active equality matches and the other index is not unique, or if not all of its components are involved in active equality matches, ABL chooses the former of the two.
    2. Select the index with more active equality matches.
    3. Select the index with more active range matches.
    4. Select the index with more active sort matches.
    5. Select the index that is the primary index.
    6. Select the first index alphabetically by index name.

- If you specify the -v6q startup parameter, the AVM might have to scan all the records in the index to find those meeting the conditions, or it might have to examine only a subset of the records. This latter case is called bracketing the index and results in more efficient access. Having selected an index as previously described, the ABL compiler examines each component as follows to see if the index can be bracketed:
  - If the component has an active equality match, ABL can bracket it, and it examines the next component for possible bracketing.
  - If the component has an active range match, ABL can bracket it, but it does not examine the remaining components for possible bracketing.
  - If the component does not have an active equality match or an active range match, ABL does not examine the remaining components for bracketing.
• If you specify the v6q parameter, any conditions you specify in the *record-phrase* that are not involved in bracketing the selected index are applied to the fields in the record itself to determine if the record meets the overall *record-phrase* criteria. For example, assume that the f table has fields a, b, and c involved in two indexes:
  
  – Primary, unique index (I1) on a, b, and c
  
  – Secondary non-unique index (I2) on c

Table 37 shows the index ABL selects and the bracketed part of the index for various *record-phrases*.

**Table 37:** Progress Version 6 index selection examples

<table>
<thead>
<tr>
<th>Record phrase</th>
<th>Index selected</th>
<th>Bracketing on</th>
</tr>
</thead>
<tbody>
<tr>
<td>f WHERE a = 3 AND b = 2 AND c = 3</td>
<td>I1</td>
<td>a + b + c</td>
</tr>
<tr>
<td>f WHERE a = 3</td>
<td>I1</td>
<td>a</td>
</tr>
<tr>
<td>f WHERE c = 1</td>
<td>I2</td>
<td>c</td>
</tr>
<tr>
<td>f WHERE a = 3 AND b &gt; 7 AND c = 3</td>
<td>I1</td>
<td>a + b</td>
</tr>
<tr>
<td>f WHERE a = 3 AND c = 4</td>
<td>I1</td>
<td>a</td>
</tr>
<tr>
<td>f WHERE b = 5</td>
<td>I1</td>
<td>None of the fields¹</td>
</tr>
<tr>
<td>f WHERE a = 1 OR b &gt; 5</td>
<td>I1</td>
<td>None of the fields¹</td>
</tr>
<tr>
<td>f WHERE (a &gt;= a1 AND a &lt;= a2) OR (a1=0)</td>
<td>I1</td>
<td>None of the fields²</td>
</tr>
<tr>
<td>f WHERE a &gt;= (IF a1 NE 0 THEN a1 ELSE -99999999) AND a &lt;= (IF a1 NE 0 THEN a2 ELSE +99999999)</td>
<td>I1</td>
<td>a²</td>
</tr>
</tbody>
</table>

¹ In this case, ABL must look at all of the records to determine which meet the specified criteria.
² The two record phrases in these examples are almost identical in effect, but the one using the OR operator to connect conditions is much less efficient in its use of the selected index.

• The **FIRST** and **LAST** keywords are especially useful when you are sorting records in a table in which you want to display information. Often, several related records exist in a related table, but you only want to display the first or last related record from that table in the sort. You can use **FIRST** or **LAST** in these cases.

Suppose you were interested in displaying the date when each Customer first placed an order. This procedure displays the Customer number and date of the first Order:

```
FOR EACH Customer NO-LOCK, FIRST Order OF Customer NO-LOCK:
  DISPLAY Order.CustNum Order.OrderDate.
END.
```
The following procedure displays the last Order Line of every Order, sorted by the Price of the Item and by the Promised Date of the Order:

DISPLAY "Show the last order-line of each order," SKIP "sorted by the item’s price and the" SKIP "promised date of the order." WITH CENTERED.

FOR EACH Order NO-LOCK, LAST OrderLine OF Order NO-LOCK,
   Item OF OrderLine NO-LOCK BY Item.Price BY Order.PromiseDate:
   Order.PromiseDate WITH TITLE "For FIRST/LAST" CENTERED.
END.

- If you want the AVM to use a specific index, you must specify the first component of that index in the record phrase of the FOR statement.
- You cannot reference a BLOB or CLOB field in a WHERE clause.
- For more information on the FOR statement, see OpenEdge Getting Started: ABL Essentials.
- For SpeedScript, the on-endkey-phrase and the on-quit-phrase do not apply.

**See also**
CATCH statement, FINALLY statement, FIND statement, Frame phrase, ON ENDKEY phrase, ON ERROR phrase, ON QUIT phrase, ON STOP phrase, Record phrase

**FORM statement**

Defines the layout and certain processing attributes of a frame for use within a single procedure. If the frame has not been previously scoped, the FORM statement scopes it to the current block. Use the FORM statement if you want to describe a frame in a single statement rather than let ABL construct the frame based on individual data handling statements in a block. You can use the FORM statement to describe a layout for a data iteration and the frame header or background.

**Syntax**

```
FORM
  [ form-item ... ]
  [ { HEADER | BACKGROUND } head-item ... ]
  [ frame-phrase ]
FORM record [ EXCEPT field ... ] [ frame-phrase ]
```

*form-item*

Specifies a field-level widget or value to display in the frame, or a SPACE or SKIP directive. The data specified by all form items are owned by a single field group, duplicated for each data iteration in the frame.

This is the syntax for *form-item:*
FORM statement

Syntax

```
field [ format-phrase ]
```

```
constant
  [ at-phrase | TO n ]
  [ BGCOLOR expression ]
  [ DCOLOR expression ]
  [ FGCOLOR expression ]
  [ FONT expression ]
  [ PFCOLOR expression ]
  [ VIEW-AS TEXT ]
  [ WIDGET-ID id-number ]
```

```
SPACE [ ( n ) ]
```

```
SKIP [ ( n ) ]
```

field

A reference to a field or variable to be displayed in the frame. This value cannot be an expression or a frame. To specify a child frame, you must first define the parent and child frames, then assign the FRAME attribute of the child frame to the handle of the parent frame. The child frame is assigned to the same field group as other form items.

format-phrase

Specifies one or more frame attributes for a field or variable. For more information on format-phrase, see the Format phrase reference entry.

constant

A constant value.

at-phrase

Specifies the location of a value within the frame. The AT phrase does not left justify the data; it simply indicates the placement of the data area. This is the syntax for the AT phrase:
### Syntax

```
AT { n
    | { COLUMN column | COLUMN-OF relative-position }
    | { ROW row | ROW-OF relative-position }
    | { COLON-ALIGNED | LEFT-ALIGNED | RIGHT-ALIGNED }
    | { X x | X-OF relative-position }
    | { Y y | Y-OF relative-position }
    | { COLON-ALIGNED | LEFT-ALIGNED | RIGHT-ALIGNED }
}
```

For more information, see the AT phrase reference entry.

**TO n**

The number \( n \) of the column in which you want the display to end. The TO option does not right justify the data; it simply indicates the placement of the data area.

**BGCOLOR expression**

Specifies the background color of the form item in graphical interfaces. This option is ignored in character interfaces.

**DCOLOR expression**

Specifies the display color of the form item in character interfaces. This option is ignored in graphical interfaces.

**FGCOLOR expression**

Specifies the foreground color of the form item in graphical interfaces. This option is ignored in character interfaces.

**FONT expression**

Specifies the font of the form item.

**PFCOLOR expression**

Specifies the prompt color of the form item in character interfaces. This option is ignored in graphical interfaces.

**VIEW-AS TEXT**

Specifies that the form item be displayed as a TEXT widget rather than as a FILL-IN widget.

**WIDGET-ID id-number**

Specifies a widget ID for a field-level widget or value to display in a frame. The value of \( id-number \) must be an expression that evaluates to an even integer value between 2 and 65534, inclusive, and must be unique across all widget IDs in the window or dialog box.

If you specify an invalid ID, the compiler displays an error message. This option is supported in graphical interfaces only, and only in Windows.
SPACE ( n )

Identifies the number (n) of blank spaces to insert after the displayed expression. The n can be 0. If the number of spaces you specify is more than the spaces left on the current line of the frame, the AVM starts a new line and discards extra spaces. If you do not use this option or you do not use n, the AVM inserts one space between items in the frame.

SKIP ( n )

Identifies the number (n) of blank lines to insert after the displayed expression. The number of blank lines can be can be 0. If you do not use this option, the AVM does not skip a line between expressions unless the expressions do not fit on one line. If you use the SKIP option but do not specify n, or if n is 0, the AVM starts a new line unless it is already at the beginning of a new line.

record

Represents the name of the record you want to display. Naming a record is shorthand for listing each field individually, as a form item.

EXCEPT field . . .

Tells the AVM to display all the fields in the frame except those fields listed in the EXCEPT phrase.

HEADER

Tells the AVM to place the following items in a header section at the top of the frame in a separate field group from all other data. In addition to fields, variables, and constants, the frame header can contain expressions, images, and rectangles. The AVM reevaluates these expressions each time it displays the frame.

When you use the FORM statement with the HEADER option, ABL disregards Data Dictionary field labels for fields you name in the FORM statement. Use character strings to specify labels for fields you name in the frame header.

BACKGROUND

Specifies that any following frame items display in the frame background, behind the data and header in a separate field group. Typically, this option is used to display images or rectangles behind the data.

head-item

A description of a value to be displayed in the frame header or background, or a SPACE or SKIP directive. This is the syntax for head-item:

**Syntax**

```
expression [ format-phrase ]
```
This is exactly the same as the syntax for a form-item, except that a head-item can be an expression and does not include the PFCOLOR option. If you use an expression in a HEADER or BACKGROUND phrase, the expression is evaluated each time the frame is viewed. If you give the PAGE-TOP or PAGE-BOTTOM option for the frame, the expression is evaluated for each page. This allows you, for example, to include a reference to the PAGE-NUMBER function in the frame header.

**Note:** If head-item is an expression, any option of the format-phrase may be used with it; if head-item is a constant, only the AT phrase, TO, BGCOLOR, DCOLOR, FGCOLOR, FONT, VIEW-AS TEXT, and WIDGET-ID options are allowed.

---

**Examples**

This procedure lets the user update information on a specific Customer. The FORM statement describes a very specific layout for the UPDATE statement to use.

**r-form.p**

```plaintext
REPEAT FOR Customer:
FORM
  Customer.Name COLON 10 Customer.Phone COLON 50
  Customer.Address COLON 10 Customer.SalesRep COLON 50 SKIP
  Customer.City COLON 10 NO-LABEL Customer.State NO-LABEL
  Customer.PostalCode NO-LABEL
  WITH SIDE-LABELS 1 DOWN CENTERED.
PROMPT-FOR Customer.CustNum WITH FRAME cnum SIDE-LABELS CENTERED.
FIND Customer USING Customer.CustNum.
END.
```
When you use the FORM statement to control the order in which fields appear on the screen, remember that this order is independent of the order in which the AVM processes the fields during data entry.

In the example, the above FORM statement displays the customer name first and the phone number second. But the UPDATE statement specifies the phone number after the name, address, city, state, and postal-code. The fields are displayed as described in the FORM statement, but the tab order is determined by the UPDATE statement.

The following example uses the HEADER option:

**r-eval.p**

```abl
DEFINE VARIABLE ix AS INTEGER NO-UNDO FORMAT ">9".
FORM HEADER "This is the header - ix is" ix
   WITH FRAME a ROW ix COLUMN ix ix DOWN.
DO ix = 1 TO 8 WITH FRAME a
   DISPLAY ix.
   PAUSE.
END.
```

The FORM statement defines a HEADER frame that consists of the text “This is the header - ix is” and the value of the variable ix. In addition, it also specifies a screen location where the header is displayed. The FORM statement does not bring the header frame into view.

On the first iteration of the DO block, the DISPLAY statement brings the frame into view. On the second iteration of the DO block, the frame is already in view (it was not hidden during the first iteration), so the header of the frame is not re-evaluated. Thus, the new value of ix is not reflected in the header portion of the frame, and you do not see the new value of ix in the header. You also do not see the position of the frame on the screen change.

In contrast, look at this modified version of the procedure:

**r-eval2.p**

```abl
DEFINE VARIABLE ix AS INTEGER NO-UNDO FORMAT ">9".
FORM HEADER "This is the header - ix is" ix
   WITH FRAME a ROW ix COLUMN ix ix DOWN.
DO ix = 1 TO 8 WITH FRAME a:
   DISPLAY ix.
   HIDE FRAME a.
END.
```

On the first iteration of the DO block, the DISPLAY statement displays the frame. The HIDE statement removes the frame from the window. Therefore, on the second iteration of the DO block, the DISPLAY statement redisplays the frame. The AVM re-evaluates the header of the frame each time the frame is redisplayed. Therefore, the header of the frame reflects the change to i, and the position of the frame in the window also changes.

**Notes**

- When you use any of the statements that access the screen, you can name a frame or use the default frame for the block where the statements appears. For more information on frame scoping, see *OpenEdge Getting Started: ABL Essentials.*
• When ABL compiles a procedure, it makes a top-to-bottom pass of the procedure to design all the frames for that procedure, including those referenced in FORM statements. ABL adds field and format attributes as it goes through the procedure.

• If you have enabled application-defined widget IDs in your ABL GUI application, by specifying the Use Widget ID (–usewidgetid) startup parameter, then the AVM uses the value specified in the WIDGET-ID option to set the WIDGET-ID attribute for this widget when it creates the widget at run time, instead of using the widget ID it normally generates by default. If you have not enabled application-defined widget IDs, then the AVM ignores this option setting at run time.

For more information about the WIDGET-ID attribute, see its reference entry in the “Handle Attributes and Methods Reference” section on page 1271. For more information about the Use Widget ID (–usewidgetid) startup parameter, see OpenEdge Deployment: Startup Command and Parameter Reference.

• If you use a single qualified identifier with the FORM statement, the compiler first interprets the reference as dbname.tablename. If the compiler cannot resolve the reference as dbname.tablename, it tries to resolve it as tablename.fieldname. When naming fields in a FORM statement, you must use table names that are different from field names to avoid ambiguous references. See the Record phrase reference entry for more information.

• To use the FORM statement to display a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

• If you define a frame to use as a DDE frame, you must realize the frame (display it) before using it as a conversation end-point. If you want the DDE frame to remain invisible during its use in a DDE conversation, set its HIDDEN attribute to TRUE after realizing the frame.

For information on DDE frames, see OpenEdge Development: Programming Interfaces.

See also DEFINE FRAME statement, Format phrase, Frame phrase

Format phrase

Specifies one or more attributes for a widget.
### Syntax

```
[ at-phrase ]
[ AS datatype | LIKE field ]
[ ATTR-SPACE | NO-ATTR-SPACE ]
[ AUTO-RETURN ]
[ BGCOLOR expression ]
[ BLANK ]
[ COLON n | TO n ]
[ COLUMN-LABEL label ]
[ DEBLANK ]
[ DCOLOR expression ]
[ DISABLE-AUTO-ZAP ]
[ FGCOLOR expression ]
[ FONT expression ]
[ FORMAT string ]
[ HELP string ]
[ LABEL label[ , label ] ... | NO-LABELS ]
[ NO-TAB-STOP ]
[ PFCOLOR expression ]
[ VALIDATE ( condition, msg-expression ) ]
[ view-as-phrase ]
[ WIDGET-ID id-number ]
```

### at-phrase

The column, row and column, or x and y pixel location you want the display to start. The AT option does not left justify the data; it simply indicates the placement of the data area.

### AS datatype

Creates a frame field and variable with the data type you specify. This is useful for defining display positions in a frame for use with DISPLAY @ field.

### LIKE field

Creates a frame field and variable with the same definition as field.
The LIKE option in a DEFINE VARIABLE statement, DEFINE WORK-TABLE statement, or Format phrase requires that a particular database is connected. Since you can start up an ABL application session without connecting to a database, use the LIKE option with caution.

**ATTR-SPACE | NO-ATTR-SPACE**

Has no effect; supported only for backward compatibility.

**AUTO-RETURN**

Causes the AVM to automatically move out of a field as if you pressed RETURN. When you enter the last character in the field, the AVM automatically moves out of the field. If this happens on the last field of a data entry statement, the AVM functions as if you pressed GO.

For the purposes of AUTO-RETURN, entering leading zeros in a numeric field does not count as filling the field. For example, suppose you define a numeric field as follows:

```
DEFINE VARIABLE X AS INTEGER NO-UNDO FORMAT "99".
SET X AUTO-RETURN.
```

If you enter a 09 into the field, the AVM does not AUTO-RETURN. To get the AUTO-RETURN behavior in this situation, define the field as CHARACTER with a format of "99".

**BGCOLOR expression**

Specifies the background color of the widget in graphical interfaces. This option is ignored in character interfaces.

**BLANK**

Displays blanks for the field you are displaying or entering. This is useful for entering passwords.

**COLON n**

The number (n) of the column in which you want the colon of the label to appear. Use this option with SIDE-LABEL frames where the labels are placed to the left of the data and are separated from the data with a colon.

**TO n**

The number (n) of the column in which you want to end the display. The TO option does not right justify the data; it indicates the placement of the data area.

**COLUMN-LABEL label**

Names the label you want to display above the field. If you want the label to use more than one line (stacked labels), use an exclamation point (!) in the label to indicate where to break the line. For example:
The AVM does not display column labels if you use the SIDE-LABELS or the NO-LABELS option with the Frame phrase.

You must enclose the label string in quotation marks. If you want to use the exclamation point (!) as one of the characters in a column label, use two exclamation points (!!).

DEBLANK

Removes leading blanks (for use on input character fields only). Leading blanks in the value before input are not removed unless the user changes the value.

DCOLOR expression

Specifies the display color of the widget in character interfaces. This attribute is ignored in graphical interfaces.

DISABLE-AUTO-ZAP

Specifies whether the value of the AUTO-ZAP attribute will be ignored. See the AUTO-ZAP attribute reference entry. This option only applies to fill-ins.

The following example defines a frame with two fill-ins, both of which specify the DISABLE-AUTO-ZAP option:

```
DEFINE FRAME frame-a
  fill-in-1 DISABLE-AUTO-ZAP
  fill-in-2 DISABLE-AUTO-ZAP
  button-1
  WITH THREE-D SIDE-LABELS.
```

FGCOLOR expression

Specifies the foreground color of the widget in graphical interfaces. This option is ignored in character interfaces.

FONT expression

Specifies the font of the widget.

FORMAT string

Represents the format in which you want to display the expression. You must enclose string in quotation marks ("""). If you do not use the FORMAT option, ABL uses the defaults shown in Table 38.
Table 38: Default display formats

<table>
<thead>
<tr>
<th>Type of expression</th>
<th>Default format</th>
</tr>
</thead>
<tbody>
<tr>
<td>Field</td>
<td>Format from Dictionary</td>
</tr>
<tr>
<td>Variable</td>
<td>Format from variable definition</td>
</tr>
<tr>
<td>Constant character</td>
<td>Length of character string</td>
</tr>
<tr>
<td>Other</td>
<td>Default format for the data type of the expression</td>
</tr>
</tbody>
</table>

Table 39 lists the default formats for the Other expression.

Table 39: Default data type display formats

<table>
<thead>
<tr>
<th>Data type</th>
<th>Default display format</th>
</tr>
</thead>
<tbody>
<tr>
<td>CHARACTER</td>
<td>x(8)</td>
</tr>
<tr>
<td>CLASS¹</td>
<td>N/A</td>

<tr>
<td>RECID³</td>
<td>&gt;&gt;&gt;&gt;&gt;9</td>
</tr>
<tr>
<td>ROWID³</td>
<td>See the footnote at the end of this table.</td>
</tr>
</tbody>
</table>

1. If you display a class instance using the MESSAGE statement, ABL automatically invokes the ToString( ) method (provided by the Progress.Lang.Object class) on the object reference. To display a class instance in a frame (for example, using the DISPLAY statement), you must first explicitly convert the object reference to a displayable type using the INT64 function, the INTEGER function, the STRING function, or the ToString( ) method.

2. To display a HANDLE, you must first convert it using either the INT64 or INTEGER function and display the result.

3. You cannot display a MEMPTR, RAW, or ROWID value directly. However, you can convert it to a character string representation using the STRING function and display the result. A ROWID value converts to a hexadecimal string, "0x\text{hexdigits}," where \text{hexdigits} is any number of characters "0" through "9" and "A" through "F". A MEMPTR or RAW value converts to decimal integer string.
You can use the FORMAT option with the UPDATE and SET statements to store a character string that is longer than the field length you define in the Data Dictionary or in a DEFINE VARIABLE statement. This is possible because ABL stores data in variable-length fields.

```
DEFINE VARIABLE mychar AS CHARACTER NO-UNDO FORMAT "x(3)".
UPDATE mychar FORMAT "x(8)".
```

You can also use the ASSIGN statement to store data in a field or variable that is longer than the predefined format of that field or variable.

```
mychar = "abcdefgh".
```

However, the Data Dictionary load program only loads character data that is no longer than the format you defined in the Dictionary. For more information on data formats, see OpenEdge Getting Started: ABL Essentials.

HELP string

Represents a character string that you want to display whenever the user enters the frame field for the field or variable. When the user leaves the frame field, the AVM removes the help string from the message area. You must enclose the string in quotation marks ("").

If the input source is not the terminal, the AVM disregards any HELP options.

LABEL label [ , label ] . . .

Represents a character string that you want to use as a label for a field, variable, or expression. You must enclose the string in quotation marks (""). Table 40 shows the order ABL uses to determine the label for a field, variable, or expression.

<table>
<thead>
<tr>
<th>Table 40: Determining labels</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>LABEL string</strong></td>
</tr>
<tr>
<td>Field</td>
</tr>
<tr>
<td>Variable</td>
</tr>
<tr>
<td>Expression</td>
</tr>
</tbody>
</table>

**Note:** If you use side labels, Windows allows a user to transfer focus to field-level widgets by pressing **ALT** and one of the letters in the widget’s label. This is called a mnemonic. Specify the letter by preceding it with an ampersand (&) when specifying the LABEL option. Ending a label with an ampersand might produce undesired behavior. If you want a literal ampersand within a label, enter two ampersands (&&) in `label`. If you specify more than one widget with the same mnemonic, the AVM transfers focus to each of these in tab order when you make a selection.
NO-LABELS
Prevents the AVM from displaying a label for a field, variable, or expression.

NO-TAB-STOP
Specifies that the widget is not in its parent frame’s tab order.

The following example shows defining a frame with two fill-ins, both of which have the NO-TAB-STOP option specified:

```
DEFINE FRAME frame-a
  fill-in-1
  fill-in-2
  button-1 NO-TAB-STOP
  WITH THREE-D SIDE-LABELS.
```

See the TAB-STOP attribute reference entry for related information.

PFCOLOR expression
Specifies the prompt color of the widget in character interfaces. This attribute is ignored in graphical interfaces.

VALIDATE ( condition, msg-expression )
Specifies a value that you want to validate against the data entered into a screen field or variable. The condition is a Boolean expression (a constant, field name, variable name, or expression) whose value is TRUE or FALSE.

When you use the VALIDATE option to validate a specific field, any reference to that field in condition is assumed to be an input field. For example, in the following statement, the AVM assumes the PromiseDate field is an input field:

```
SET Order.OrderDate Order.PromiseDate
  VALIDATE(Order.PromiseDate > Order.OrderDate,
            "Promise date must be later than order date").
```

The previous statement is equivalent to the following statement:

```
SET Order.OrderDate Order.PromiseDate
  VALIDATE(INPUT Order.PromiseDate > Order.OrderDate,
            "Promise date must be later than order date").
```

The validation is based on the value of OrderDate prior to the SET statement. If you want to validate the value of PromiseDate against the input value of OrderDate, use this statement:

```
SET Order.OrderDate Order.PromiseDate
  VALIDATE(Order.PromiseDate > INPUT Order.OrderDate,
            "Promise date must be later than order date").
```
If you try to validate a field whose reference is ambiguous, the AVM tries to resolve the ambiguity by referencing the table that contains the record being updated. In the following example, the SalesRep field is ambiguous because it exists in both the Order table and the Customer table. The AVM resolves the ambiguity by validating the SalesRep field in the Order table, since the Order table is being updated.

```
FIND FIRST Customer.
FIND FIRST Order.
UPDATE Order.CustNum Order.SalesRep
  VALIDATE(LENGTH(Order.SalesRep) > 1, "Invalid sales rep value.").
```

If the reference is to an array field and has no subscript, the AVM assumes you want to use the subscript of the field that is being prompted.

If the value of `condition` is FALSE, use `msg-expression` to display a specific message. You must enclose `msg-expression` in quotation marks (" ").

The AVM processes validation criteria whenever the user attempts to leave the frame field. If the frame field value is not valid, the AVM displays `msg-expression` in the message area, causes the terminal to beep, and does not advance out of the frame field.

If you tab a frame field, make no changes, and leave the field, the AVM does not process the validation criteria specified with the `VALIDATE` option until the you press `GO (F1)`. If you press `ENDKEY` or `END-ERROR`, or an error occurs, the AVM does not test the validation criteria specified with the `VALIDATE` option.

If the input source for the procedure is a table, the AVM validates each input field (except those with a value of "."). If the result of the validation is FALSE, `msg-expression` is displayed and the AVM treats the validation as an error.

To suppress the Data Dictionary validation criteria for a field, use this `VALIDATE` option:

```
VALIDATE(TRUE,"")
```

When you use the `VALIDATE` option in a procedure to specify validation criteria for a field, that validation criteria applies to all other references to that field in the same frame:

```
FOR EACH Order:
  UPDATE Order.OrderDate.
  UPDATE Order.OrderDate
    VALIDATE(Order.OrderDate LE TODAY, "Can't be later than today").
END.
```

In this example, the AVM applies the validation criteria on the second `UPDATE` statement. The AVM also applies the validation criteria to the first `UPDATE` statement because both `UPDATE` statements use the same frame. Scope references to the same field to different frames if you do not want a `VALIDATE` option to affect all references to that field.

`view-as-phrase`

Specifies the type of widget. This is the syntax for `view-as-phrase`:
Syntax

```
VIEW-AS {  editor-phrase
            | FILL-IN [ NATIVE ] [ size-phrase ]
            | radio-set-phrase
            | selection-list-phrase
            | slider-phrase
            | TEXT [ size-phrase ]
            | TOGGLE-BOX [ size-phrase ]
}
```

For more information on `view-as-phrase`, see the VIEW-AS phrase reference entry.

**WIDGET-ID id-number**

Specifies a widget ID for a field or variable widget to display in a frame. The value of `id-number` must be an expression that evaluates to an even integer value between 2 and 65534, inclusive, and must be unique across all widget IDs in the window or dialog box.

If you specify an invalid ID, the compiler displays an error message. This option is supported in graphical interfaces only, and only in Windows.

**Example**

This procedure lets the user update Customer records after entering the password “secret.” The format phrase on the Phone field describes the display format of that field.

```
r-frmat.p
```

```
DEFINE VARIABLE password AS CHARACTER NO-UNDO.

UPDATE password FORMAT "x(6)" BLANK
    VALIDATE(password = "secret", "Sorry, wrong password")
    HELP "Maybe the password is 'secret' !"
    WITH FRAME passw CENTERED SIDE-LABELS.
HIDE FRAME passw.

REPEAT:
    FIND Customer USING Customer.CustNum.
    UPDATE
        Customer.Name LABEL "Customer Name" COLON 20
        VALIDATE(Customer.Name NE ",", "Please enter a name")
        Customer.Address HELP "Please enter two lines of address"
        COLON 20 LABEL "Address"
        Customer.Address2 NO-LABEL COLON 20
        Customer.City COLON 20
        Customer.State COLON 20
        Customer.PostalCode COLON 20 SKIP(3)
        Customer.Phone AT 5 FORMAT ",(999) 999-9999"
        Customer.Contact TO 60
    WITH CENTERED SIDE-LABELS.
END.
```

**Notes**

- The ATTR-SPACE/NO-ATTR-SPACE designation in a Frame phrase takes precedence over an ATTR-SPACE/NO-ATTR-SPACE designation in a Format phrase. The ATTR-SPACE/NO-ATTR-SPACE designation in a Format phrase takes precedence over an ATTR-SPACE/NO-ATTR-SPACE designation in a COMPILE statement.
If you have enabled application-defined widget IDs in your ABL GUI application, by specifying the Use Widget ID (–usew i dgeti d) startup parameter, then the AVM uses the value specified in the WIDGET-ID option to set the WIDGET-ID attribute for this widget when it creates the widget at run time, instead of using the widget ID it normally generates by default. If you have not enabled application-defined widget IDs, then the AVM ignores this option setting at run time.

For more information about the WIDGET-ID attribute, see its reference entry in the “Handle Attributes and Methods Reference” section on page 1271. For more information about the Use Widget ID (–usew i dgeti d) startup parameter, see OpenEdge Deployment: Startup Command and Parameter Reference.

For SpeedScript, these options are invalid: BGCOLOR, DCOLOR, FGCO LOR, FONT, PFCOLOR, view-as-phrase.

With respect to internationalization, some double-byte and UTF-8 multi-byte characters display and print in one or two columns. Each unit in the format string represents one physical column. To display or print a character that requires two columns, the FORMAT phrase must specify two columns. For more information, see OpenEdge Development: Internationalizing Applications.

See also FORM statement, Frame phrase

Frame phrase

Specifies the overall layout and processing properties of a frame for frame definition (DEFINE FRAME and FORM), block header (DO, FOR EACH, and REPEAT), and data handling (DISPLAY, SET, etc.) statements. When used on block header statements, the Frame phrase also specifies the default frame for data handling statements within the block. Frame phrases can also be used on individual data handling statements to indicate the specific frame where the statement applies.
Syntax

WITH [ ACCUM [ max-length ] ]
[ at-phrase ] [ ATTR-SPACE | NO-ATTR-SPACE ]
[ CANCEL-BUTTON button-name ] [ CENTERED ]
[ color-specification ]
[ COLUMN expression ] [ n COLUMNS ]
[ CONTEXT-HELP ] [ CONTEXT-HELP-FILE help-file-name ]
[ DEFAULT-BUTTON button-name ]
[ DROP-TARGET ]
[ expression ] DOWN [ EXPORT ]
[ WIDGET-ID id-number ] [ FONT expression ]
[ FRAME frame ]
[ INHERIT-BGCOLOR | NO-INHERIT-BGCOLOR ]
[ INHERIT-FGCOLOR | NO-INHERIT-FGCOLOR ]
[ KEEP-TAB-ORDER ] [ NO-BOX ]
[ NO-HIDE ] [ NO-LABELS ] [ USE-DICT-EXPS ]
[ NO-VALIDATE ] [ NO-AUTO-VALIDATE ]
[ NO-HELP ] [ NO-UNDERLINE ]
[ OVERLAY ] [ PAGE-BOTTOM | PAGE-TOP ] [ RETAIN n ]
[ ROW expression ] [ SCREEN-IO | STREAM-IO ]
[ SCROLL n ] [ SCROLLABLE ] [ SIDE-LABELS ]
[ size-phrase ] [ STREAM stream | STREAM-HANDLE handle ] [ THREE-D ]
[ title-phrase ] [ TOP-ONLY ] [ USE-TEXT ]
[ V6FRAME [ USE-REVVIDEO | USE-UNDERLINE ] ]
[ VIEW-AS DIALOG-BOX ] [ WIDTH n ] [ IN WINDOW window ]

ACCUM [ max-length ]

The ACCUM option lets you use aggregate functions (such as MAX, MIN, TOTAL, and SUBTOTAL) to accumulate values within shared frames. With the ACCUM option, aggregate values can be shared among procedures through shared frames. You must include the ACCUM option in the FORM statement or DEFINE FRAME statement of each procedure that uses the shared frame.

The following procedure defines a new shared frame:

DEFINE NEW SHARED FRAME x.
FORM field1 field2 WITH FRAME x ACCUM.
RUN testb.p.

The following procedure uses the shared frame:

...
When you specify a user-defined aggregate label, use the max-length parameter of the ACCUM option to specify a maximum aggregate label length in the frame phrases of shared frames. For more information, see the Aggregate phrase reference entry.

at-phrase

Specifies the position of the frame (upper-left corner) within a window or parent frame. This is the syntax for the AT phrase for a frame:

Syntax

```
AT { COLUMN column ROW row
     | X x Y y
   }
```

Note that for a frame parented by a window, you must specify an absolute position relative to the display area of the window. For a frame parented by another frame, you must specify a position relative to the display area of the parent frame. The default value for all AT phrase parameters is 1. ABL ignores the COLUMN or X option if you use the CENTERED option for the same frame. For more information on at-phrase, see the AT phrase reference entry.

ATTR-SPACE | NO-ATTR-SPACE

Has no effect; supported only for backward compatibility.

CANCEL-BUTTON button-name

Specifies the cancel button for the frame. This is the button chosen when the ESC key code is applied to the frame in Windows. This button might also be chosen when the ESC key code is applied to a frame within the same frame family that does not have a cancel button. In such an event, the AVM searches the frame family in random order. The first cancel button found during this random search is chosen. The button-name argument must be a static button name.

CENTERED

Centers the frame horizontally in the window or frame to which it is parented (or the terminal display, in character mode). If you use the CENTERED option and are sending output to a device other than the terminal, the AVM centers the frame for the terminal. This might result in a non-centered frame on the alternate output device.

You can also use the AT phrase or COLUMN option to specify the position of the frame.
**color-specification**

For a graphical user interface, specifies the foreground and background color of the frame; for a character interface, specifies the display and prompt colors for the frame.

**Syntax**

\[
\begin{align*}
\{ & \{ \text{BGCOLOR} \ expression \} \\
& \{ \text{DCOLOR} \ expression \} \\
& \{ \text{FGCOLOR} \ expression \} \\
& \{ \text{PFCOLOR} \ expression \} \\
\} \\
\{ & \{ \text{COLOR} \ [ \text{DISPLAY} ] color-phrase \\
& \{ \text{PROMPT} color-phrase \} \\
\} \\
\}
\end{align*}
\]

For graphical interfaces, the FGCOLOR and BGCOLOR options specify the foreground and background color of the frame. These options are not supported in character interfaces. For character interfaces, use the DCOLOR and PFCOLOR options (which are not supported in graphical interfaces) to specify the display color and prompt color of the frame.

The COLOR option is obsolete, but is retained for backward compatibility.

Widgets (except child frames) within the frame inherit the colors of the frame by default. You can also set the colors of each widget individually.

**COLUMN expression**

The *expression* is a constant, field name, variable name or expression whose value is the number of the column, relative to the window or parent frame in which you place the frame. The default value is 1. ABL ignores this option if you use the CENTERED option for the same frame.

The AVM evaluates *expression* each time the frame comes into view or is printed at the top or bottom of a page (if the frame is a PAGE-TOP or PAGE-BOTTOM frame). For more information, see the *expression* option of the FORM statement.

**n COLUMNS**

Formats data fields into a specific number (*n*) of columns. Truncates labels to 16, 14, and 12 characters when the number of columns is 1, 2, or 3, respectively. ABL reserves a fixed number of positions in each column for labels. For *n* = 1, 16 positions are allowed for a label; for *n* = 2, 14 positions are allowed; and for *n* = 3, 12 positions are allowed. Label positions include room for a colon and a space after the label. Labels are right justified if they are short, and truncated if they are too long. By default, the AVM wraps fields across the frame for as many lines as required, placing labels above the fields.

When you use this option, it implies SIDE-LABELS and overrides any AT, COLON, TO, or SPACE options you might have used in the same Frame phrase.
Frame phrase

CONTEXT-HELP

Specifies that context-sensitive help is available for this frame. This option is valid in Windows GUI only.

CONTEXT-HELP-FILE help-file-name

Specifies the complete path name of a help (.HLP) file associated with this frame. If CONTEXT-HELP-FILE is specified without CONTEXT-HELP, CONTEXT-HELP is assumed. This behavior can be overridden by setting the dialog box’s CONTEXT-HELP attribute to FALSE at run time. This option is valid in Windows GUI only.

DEFAULT-BUTTON button-name

Specifies a default button for the frame. This is the button chosen when the ENTER key code in Windows is invoked for the frame. This button might also be chosen when the ESC key code is applied to a frame within the same frame family that does not have a default button. In such an event, the AVM searches the frame family in random order. The first default button found during this random search is chosen. The button-name argument must be the name of a static button. This button must be defined with the DEFAULT option and cannot display an image.

DROP-TARGET

Indicates whether you want to be able to drop a file onto the object.

[expression] DOWN

Specifies that the frame is a down frame. A down frame is a frame that can display multiple occurrences of the set of fields defined in the frame. The expression is a constant, field name, variable name or expression whose value is the number of occurrences you want in the frame. If you specify 1 for expression, the frame is not a down frame.

Down frames are typically specified for iterative blocks. On the first iteration of the block, the AVM displays the first set of data (a record, field, or variable value) as the first occurrence in the frame. After displaying the data, the AVM advances to the next occurrence in the frame on the second iteration of the block, and displays the second set of data there. The AVM continues advancing and displaying data for the number of occurrences specified by expression, and prompts to continue with another set of occurrences until all the data has been displayed. The AVM evaluates expression each time the frame comes into view or is printed at the top or bottom of a page (if the frame is a PAGE-TOP or PAGE-BOTTOM frame). If you do not specify expression, the AVM displays as many occurrences as can fit in the current window.

If you do not use the DOWN option, ABL automatically makes certain frames down frames, unless you specify otherwise (1 DOWN). For more information on frames and down frames, see OpenEdge Getting Started: ABL Essentials.

EXPORT

This option is valid only for SQL.
WIDGET-ID  id-number

Specifies a widget ID for a frame widget. The value of id-number must be an expression that evaluates to an even integer value between 2 and 65534, inclusive, and must be unique across all widget IDs in the window or dialog box.

If you specify an invalid ID, the compiler displays an error message. This option is supported in graphical interfaces only, and only in Windows.

FONT  expression

Specifies the font of the frame. All widgets within a frame, except child frames, inherit the font of the frame by default. You can also set the font of each widget individually. By default, the AVM uses the default system font.

FRAME  frame

Defines new frames by giving them unique names. Whenever the same frame name is referred to in more than one Frame phrase, ABL combines the characteristics on each Frame phrase naming that frame. ABL also combines any frame characteristics used in data handling statements that name the same frame into the same frame description. This option is redundant for DEFINE FRAME statements. If you do not specify this option, ABL uses the default frame for the current block.

INHERIT-BGCOLOR | NO-INHERIT-BGCOLOR

Specifies whether the following field-level widgets in the frame inherit the frame’s background color: BROWSE, COMBO-BOX (all types), EDITOR, FILL-IN (NATIVE and Enabled), and SELECTION-LIST.

Specify the INHERIT-BGCOLOR option to allow field-level widgets in the frame to inherit the frame’s background color. Specify the NO-INHERIT-BGCOLOR option to prevent field-level widgets in the frame from inheriting the frame’s background color.

Specifying either of these options overrides the INHERIT-BGCOLOR attribute setting for the session. Setting the frame’s INHERIT-BGCOLOR attribute overrides the INHERIT-BGCOLOR option on the frame. Setting the BGCOLOR attribute for a field-level widget within the frame overrides any INHERIT-BGCOLOR attribute or option settings.

INHERIT-FGCOLOR | NO-INHERIT-FGCOLOR

Specifies whether the following field-level widgets in the frame inherit the frame’s foreground color: BROWSE, COMBO-BOX (all types), EDITOR, FILL-IN (NATIVE and Enabled), and SELECTION-LIST.

Specify the INHERIT-FGCOLOR option to allow field-level widgets in the frame to inherit the frame’s foreground color. Specify the NO-INHERIT-FGCOLOR option to prevent field-level widgets in the frame from inheriting the frame’s foreground color.

Specifying either of these options overrides the INHERIT-FGCOLOR attribute setting for the session. Setting the frame’s INHERIT-FGCOLOR attribute overrides the INHERIT-FGCOLOR option on the frame. Setting the FGCOLOR attribute for a field-level widget within the frame overrides any INHERIT-FGCOLOR attribute or option settings.
**KEEP-TAB-ORDER**

Prevents the frame-oriented I/O statements, ENABLE, UPDATE, SET, and PROMPT-FOR, from changing the tab order of your widgets in the frame. The tab order always remains the same as the order in which you first specify widgets in the frame. If you do not specify this option, ABL creates a new tab order based on the order specified in each frame-oriented I/O statement.

All attributes and methods that affect tab order (such as FIRST-TAB-ITEM and MOVE-AFTER-TAB), continue to change the tab order whether or not you specify this option. If you specify the option, these attributes and methods specify a new tab order for all frame-oriented I/O statements that follow.

**NO-BOX**

Does not display a box around the frame. If you do not use this option, the AVM displays a box around the data you are displaying.

If you are sending data to a device other than a terminal and you do not use this option, the AVM omits the sides and bottom line of the box and replaces the top line with blanks.

**NO-HIDE**

Suppress the automatic hiding of the frame (when the block where the frame is scoped iterates). The frame is hidden only if space is needed to display other frames.

NO-HIDE suppresses hiding for a frame only when the block where that frame is scoped iterates. For example:

```abl
FOR EACH Customer NO-LOCK:
    FOR EACH Order OF Customer NO-LOCK:
        DISPLAY Order.OrderNum.
        DISPLAY "hello" WITH FRAME b COLUMN 60 NO-HIDE.
    END.
END.
END.
```

In this example, the AVM does not hide frame b when the inner block iterates. However, it does hide frame b when the outer block iterates. If you want the frame to stay in view during iterations of the outer block, scope the frame to that block.

**NO-LABELS**

Does not display labels. This option overrides any COLUMN-LABEL option you include in another phrase or statement.

**NO-UNDERLINE**

Does not underline labels appearing above fields.

**USE-DICT-EXPS**

Ensures that validation expressions and help strings from the Data Dictionary are compiled into the application. Typically, when the ABL compiler encounters a field reference in an input statement, Data Dictionary help and validation expressions are compiled in for that field, unless the field has a HELP or VALIDATE option (format
frame) attached in the input statement (or earlier in the procedure). In this case, the custom help or validation expression is used.

In Progress Version 7 and later, there are two syntax constructs that can enable a field for input without the compiler specifically knowing about it: ENABLE ALL and `widget-name:SENSITIVE = YES`.

When ABL encounters an ENABLE ALL statement, every field in the associated frame has Data Dictionary validation expressions and help strings compiled into the application. This closes any possible validation or help hole. As a side-effect, validation expressions and help strings that are not required might be compiled, but this will not affect the application.

This behavior places two important conditions on you. First, adding a field to a frame after the first ENABLE ALL is not desirable. Data Dictionary validation and help will not be compiled for this field. Second, any custom validation or help must come before the first ENABLE ALL. A good practice is to include these in the DEFINE FRAME or FORM statements.

In the case of `widget-name:SENSITIVE = YES`, there is more potential for validation and help holes. Since the compiler cannot predict whether these statements are used, in effect, as input statements, no help or validation is compiled. USE-DICT-EXPS explicitly compiles in all validation expressions and help strings for a frame. For each frame that you use `widget-name:SENSITIVE = YES`, specify USE-DICT-EXPS. This closes any potential validation or help holes. To provide custom help or validation when using USE-DICT-EXPS, the HELP or VALIDATE option must appear in the first reference to that field. Typically, this is in the DEFINE FRAME or FORM statement.

NO-VALIDATE

Disregards all validation conditions specified in the Data Dictionary for fields entered in this frame.

NO-AUTO-VALIDATE

Tells ABL to compile into the code all relevant validations it finds in the OpenEdge Data Dictionary, but to run the validations only when the code for the frame or for a field-level child-widget of the frame specifically invokes the VALIDATE() method.

NO-HELP

Disregards all help strings specified in the Data Dictionary for fields entered in this frame.

OVERLAY

Indicates that the frame can overlay any other frame that does not use the TOP-ONLY option. If you do not use this option, the frame you are using cannot overlay other frames. If the AVM needs to display an OVERLAY frame and doing so will partially obscure a TOP-ONLY frame, it first hides the TOP-ONLY frame. Any frame parented by another frame is an OVERLAY frame within the parent frame.

This procedure uses the OVERLAY option on the Frame phrase:
**r-ovrlay.p**

```
FOR EACH Customer NO-LOCK:
    DISPLAY Customer WITH 2 COLUMNS
    TITLE "Customer Information".
FOR EACH Order OF Customer NO-LOCK:
    DISPLAY Order WITH 2 COLUMNS OVERLAY
    TITLE "Customer's Orders" ROW 7 COLUMN 10.
END.
END.
```

The procedure above displays customer information in one frame. The procedure then displays order information for the customer in a second frame that overlays the first.

**PAGE-BOTTOM**

Displays the frame at the bottom of the page each time the output ends a page.

**PAGE-TOP**

Displays the frame each time the output begins on a new page.

Table 41 shows how the PAGE-TOP and PAGE-BOTTOM options work depending on the kind of DISPLAY or VIEW.

<table>
<thead>
<tr>
<th>Table 41: Using PAGE-TOP and PAGE-BOTTOM frames</th>
</tr>
</thead>
<tbody>
<tr>
<td><img src="image" alt="Table 41" /></td>
</tr>
</tbody>
</table>

**RETAIN n**

Specifies the number of frame iterations to retain when the frame scrolls on the screen. The $n$ must be a constant. For example, RETAIN 2 causes the AVM to display the last two iterations in a down frame at the top of the frame. If you are using UP to scroll up a window, those two lines are displayed at the bottom of the window. Do not use the
SCROLL option in a Frame phrase in which you also use the RETAIN option. By default, the AVM does not retain any iterations in the window that have already been displayed.

Row expression

The expression is a constant, field name, variable name, function reference, or expression whose value is the row, relative to the window or parent frame in which you place the frame. If you are displaying a frame on a device other than a terminal, this option has no effect. By default, the AVM displays a root frame at the next available row of the window and displays a child frame at row 1 of the parent frame.

The AVM evaluates expression each time the frame comes into view or is printed at the top or bottom of a page (if the frame is a PAGE-TOP or PAGE-BOTTOM frame).

For more info, see the expression option of the FORM statement.

[ SCREEN-IO | STREAM-IO ]

If you specify STREAM-IO for a frame, the USE-TEXT option is assumed and all font specifications are ignored. The frame is formatted using a fixed font in a manner appropriate for streaming to a text file or printer. In particular, all border padding for FILL-IN widgets is dropped and the default system font is used.

If you use the STREAM-IO option on the COMPILE statement, this behavior is the default for all frames in the procedure. In this case, you can override that option by specifying SCREEN-IO for an individual frame.

SCROLL n

Displays a scrolling frame rather than a paging frame. The value n is a constant that specifies the number of frame iterations to scroll when the frame scrolls in the window. For example, if a procedure uses a DISPLAY or DOWN statement when a scrolling frame is full, the data in the frame scrolls up n iterations (rather than clearing and repainting the frame as it would without the SCROLL option).

This procedure uses the SCROLL option to scroll the display one line at a time:

r-fphrsc.p

```
FOR EACH Customer NO-LOCK WHERE Customer.CustNum <= 50:
  DISPLAY Customer.CustNum Customer.Name Customer.CreditLimit
  WITH SCROLL 1 USE-TEXT.
  IF Customer.CreditLimit >= 50000 THEN
    COLOR DISPLAY MESSAGES Customer.CreditLimit.
  END.
```

Do not use the RETAIN option in a Frame phrase in which you also use the SCROLL option.

SCROLLABLE

If you specify this option, the virtual size of the frame might exceed the physical space allocated for it in the window. If that happens, scrolling is enabled for the frame. If you omit this option, the physical and virtual size of the frame are always the same and scrolling is never enabled for the frame.
SIDE-LABELS

Displays field labels to the left of and centered against the data, separated from the data by a colon (:) and a space. If you do not use the SIDE-LABELS option, the AVM displays labels above their corresponding fields in the frame header and separates the labels from the field values with underlining.

size-phrase

Specifies the size of the frame. This is the syntax for size-phrase:

Syntax

```
{ SIZE | SIZE-CHARS | SIZE-PIXELS } width BY height
```

For more information on size-phrase, see the SIZE phrase reference entry.

STREAM stream

Allows you to specify the name of a stream for SQL statements.

STREAM-HANDLE handle

Specifies the handle to a stream. If handle it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams and stream handles.

THREE-D

Specifies that the frame and all contained widget appear in three-dimensional format (Windows only). If you specify the THREE-D option for a frame, the default background color is gray rather than the window color. Frames do not inherit the THREE-D setting from a parent window, and child frames do not inherit the THREE-D setting from a parent frame.

title-phrase

Displays a title as part of the top line of the box around a display frame. Following is the syntax for the title-phrase:

Syntax

```
TITLE
   [ { [ BGCOLOR expression ] ]
   [ DCOLOR expression ]
   [ FCOLOR expression ]
   }
   [ COLOR color-phrase ]
   [ FONT expression ] title-string
```

The title-string is a constant, field name, variable name, or expression whose result is a character value. The expression is the value you want to display as a title. If title-string is a constant character string, it must be surrounded by quotes (""). The AVM automatically centers title-string in the top line of the frame box.
The BGCOLOR, FGColor, COLOR, and FONT options have no effect and are supported for backward compatibility only.

You can use the DCOLOR option to specify the color of the title in a character interface.

**TOP-ONLY**

Indicates that no other frame can overlay this frame. If you do not use this option, other frames that use the OVERLAY option can overlay this frame. If the AVM has to display an OVERLAY frame and by doing so will partially obscure a TOP-ONLY frame, it first hides the TOP-ONLY frame. See also the OVERLAY attribute reference entry.

**USE-TEXT**

Specifies that the default widget type for all widgets in the frame is TEXT rather than FILL-IN. Thus, all border padding on the widgets is dropped.

**V6FRAME [ USE-REVVIDEO | USE-UNDERLINE ]**

The V6FRAME option is designed specifically to compile and run Progress Version 6 applications with Progress Version 7 or later in Windows. This option uses the V6FontNumber setting in the [Startup] section of the current environment to calculate the height and width of a character unit and then set the layout grid used to compile frames for display in Progress Version 7 or later.

At run time, the FONT attribute for a frame compiled with the V6FRAME option is set to the font number specified with the V6FontNumber setting. The default setting for the V6FontNumber setting is 3.

By default, V6FRAME displays a border around a fill-in field. This means that your code requires more space on the screen than in Progress Version 6. You can override this behavior with one of the following options:

- **USE-REVVIDEO** displays no border around a fill-in field. When a fill-in is enabled for input, the color of the fill-in changes to the color specified with the INPUT setting in the [Colors] section in the current environment. The IBEAM cursor signals that a fill-in field has input focus.

- **USE-UNDERLINE** displays no border around a fill-in widget. When a fill-in is enabled for input, the underline attribute of the font (V6FontNumber) for the fill-in is turned on. The color of a fill-in enabled for input does not change. The IBEAM cursor signals that a fill-in field has input focus.

The V6FRAME option also limits the vertical size of a frame title to one character unit based upon the layout grid. The text of the frame title is in the font specified with the V6FontNumber setting in the [Startup] section of the current environment.

The V6FRAME option governs the appearance of screen output only. Use the STREAM-IO option to compile procedures that output to files and printers. If you specify the V6FRAME and STREAM-IO options in the same frame phrase, the STREAM-IO option overrides the V6FRAME option.

For more information on the environment for an ABL session, see *OpenEdge Deployment: Managing ABL Applications.*
VIEW-AS DIALOG-BOX

Specifies that the frame is displayed as a dialog box. A dialog box is a modal, one-down frame with many of the properties of a window. Like a window, a dialog box can be moved and programmatically resized, and it acquires scroll bars when it is resized smaller than its original frame dimensions. Unlike a window, it cannot be minimized or maximized; nor can it have a menu bar. As a frame-level widget, it is owned by a window and can contain a frame family, but it cannot be owned by another frame or dialog box. Because it is modal, a dialog box must be disabled before any other widgets in the application can be accessed by the user. For more information on the properties of a dialog box, and to compare them with the properties of a frame, see the “Widget Reference” section on page 1143.

WIDTH n

Specifies the number (n) of columns in a frame. If you do not use size-phrase or the WIDTH option, the width of the frame is based on the fields you are displaying, the position of the frame, and the width of the current or specified window.

IN WINDOW window

Specifies the window in which the frame is displayed. The value window must be the handle of a window. This option is not allowed in a DISABLE statement. By default, the AVM displays the frame in the current window.

Examples

The r-frame.p procedure displays the CustNum, Name, and Phone number for each Customer record. The frame phrase (starting with the word WITH) describes the frame being used to display that information.

```
FOR EACH Customer NO-LOCK:
  FORM HEADER
    "No-box, No-Underline, No-labels, 5 DOWN" SKIP
    "Centered" SKIP(2)
    WITH NO-BOX NO-UNDERLINE NO-LABELS CENTERED 5 DOWN.
END.
```

The r-frame2.p procedure produces a Customer report, using Customer List as the header for each page of the report and using Customer List Continued On Next Page as the footer for each page of the report. The OUTPUT TO statement directs all output to the file phone.lst. After running the r-frame2.p procedure, you can press GET then type the name of the file to view the contents of phone.lst.
**Notes**

- PAGE-TOP and PAGE-BOTTOM frames are activated based on DISPLAY or VIEW statements as previously described. They are deactivated when the block in which the frames are scoped iterates or ends.

- If you use the SIZE phrase for a down frame, then the size you specify determines the number of iterations in the frame. The number of iterations you specify with the DOWN option is ignored.

- You can input and output to a frame only when that frame is in full view. Therefore, when you input or output to a frame that is hidden or partially overlayed, the AVM displays the frame first.

- An empty WITH clause is valid. If the WITH keyword appears by itself, or in the clause following an earlier WITH, it is ignored. This feature is useful when designing template programs to be called with arguments. For example, a template program with a line like DISPLAY {1} WITH {2} executes correctly even if called with only one argument.

- The SIZE phrase and WIDTH options are mutually exclusive. If you specify WIDTH or you specify neither WIDTH nor the SIZE, the height of a frame is based on the fields you are displaying, the position of the frame, and whether or not it is a down frame.

- A frame parented by another frame cannot function as a down frame.

- If you position a child frame completely outside the virtual area of its parent frame, the AVM raises ERROR at run time when the frame is realized.

- If you position a child frame partially within the virtual area of its parent frame or the child frame is larger than the virtual area of the parent frame, the AVM crops the child frame to fit the parent’s virtual area and adds scroll bars to the child.

- If you position a child frame partially within the physical area of its parent frame or the child frame is larger than the physical area of the parent frame, the AVM adds scroll bars to the parent.

- You cannot specify the VIEW-AS DIALOG-BOX option for a frame used as a DDE frame. For information on DDE frames, see *OpenEdge Development: Programming Interfaces*.

- If you have enabled application-defined widget IDs in your ABL GUI application, by specifying the Use Widget ID (-usewidgetid) startup parameter, then the AVM uses the value specified in the WIDGET-ID option to set the WIDGET-ID attribute for this widget.
when it creates the widget at run time, instead of using the widget ID it normally generates by default. If you have not enabled application-defined widget IDs, then the AVM ignores this option setting at run time.

For more information about the WIDGET-ID attribute, see its reference entry in the “Handle Attributes and Methods Reference” section on page 1271. For more information about the Use Widget ID (-usewidgetid) startup parameter, see OpenEdge Deployment: Startup Command and Parameter Reference.

- See OpenEdge Getting Started: ABL Essentials for more information on frames.
- For SpeedScript, WebSpeed evaluates the Frame phrase as though you were running a character client. The typical WebSpeed application does not use frames when defining layout. However, if you are using existing ABL code that includes frame layouts, you can iterate through frame children to retrieve validation expressions and help strings. Generally, in SpeedScript programming, the frame serves as a virtual container for widgets. These options are invalid: ATTR-SPACE, NO-ATTR-SPACE, CENTERED, CONTEXT-HELP, CONTEXT-HELP-FILE, DEFAULT-BUTTON, SCROLLBAR VERTICAL, V6FRAME, USE-REVVIDEO, USE-UNDERLINE, VIEW-AS DIALOG-BOX, IN WINDOW.

See also
DEFINE FRAME statement, FORM statement, Format phrase, FRAME-COL function, FRAME-DOWN function, FRAME-LINE function, FRAME-ROW function, Stream object handle

FRAME-COL function

Returns a DECIMAL value that is the column position of the left corner of a frame within its window.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
FRAME-COL [ ( frame ) ]
```

frame

The name of the frame whose column position you are trying to determine. If you do not supply a frame name, the FRAME-COL function uses the default frame for the block it is in. If the FRAME-COL function is in a DO block, the function uses the default frame scoped to the block containing the DO block.

**Example**

This procedure displays Customer information in one frame, then displays Order information in an overlay frame. FRAME-ROW places the overlay frame on the ninth row of the second column. FRAME-COL places the overlay frame on the first column of the first frame.
The FRAME-COL function returns a value of 0 if the frame you specify is not in view when the AVM evaluates the function.

To convert the decimal value returned by FRAME-COL to an integer value, use the INTEGER function.

See also Frame phrase, FRAME-DOWN function, FRAME-LINE function, FRAME-ROW function, INTEGER function

**FRAME-DB function**

Returns the logical database name of the database that contains any field in which the user-interface cursor is entered.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```plaintext
FRAME-DB
```

The function requires no arguments. If the cursor is in a field that is not a database field, this function returns no value for the field.

**Example**

For each field being updated, this procedure displays the field name, the table the field belongs to, and the database in which the table exists. The EDITING phrase is part of the UPDATE statement; it displays information on the field as you update the record, and then reads each of the keystrokes entered (READKEY) and applies those keystrokes (APPLY LASTKEY).
FRAME-DOWN function

Notes

• If the cursor is not in an enabled input field when the last input statement is executed, or the input field is not associated with a database field, FRAME-DB returns an empty string.

• Use this syntax to find the name of a schema holder for a non-OpenEdge database:

  \[
  \text{SDBNAME ( FRAME-DB )}
  \]

DBCODEPAGE function, DBCOLLATION function, FRAME-FIELD function, FRAME-FILE function, FRAME-INDEX function, LDBNAME function, PROGRAM-NAME function, SDBNAME function

FRAME-DOWN function

Returns an INTEGER value that represents the number of iterations in a frame.

**Note:** Does not apply to SpeedScript programming.

Syntax

\[
\text{FRAME-DOWN [ ( frame ) ]}
\]

**frame**

The name of the frame whose number down you are trying to determine. If you do not supply a frame name, the FRAME-DOWN function uses the default frame for the block it is in. If the FRAME-DOWN function is in a DO block, the function uses the default frame scoped to the block containing the DO block.

Example

This procedure displays Customers in a frame. When the frame is full, the procedure prompts “Do you want to see the next page?” The procedure recognizes that the frame is full when the value of FRAME-LINE (current logical line number) equals the value of FRAME-DOWN (number of iterations in the frame).

\[ \text{r-frdown.p} \]

```
DEFINE VARIABLE ans AS LOGICAL NO-UNDO.
REPEAT:
  FIND NEXT Customer NO-LOCK.
  IF FRAME-LINE = FRAME-DOWN THEN DO:
    MESSAGE "Do you want to see the next page ?" UPDATE ans.
    IF NOT ans THEN LEAVE.
  END.
END.
```

**Note**

The FRAME-DOWN function returns a value of 0 if used with a single frame or if the frame is not in view when the function is evaluated.

See also

Frame phrase, FRAME-COL function, FRAME-LINE function, FRAME-ROW function
**FRAME-FIELD function**

During a data entry statement, returns the name of the input field the cursor is in. At other times, returns the name of the input field the cursor was last in.

The FRAME-FIELD function is particularly useful if you want to provide the user with help for the input field being used.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
FRAME-FIELD
```

**Example**

For each field the user is updating, this procedure displays the name of the field, the table the field belongs to, and the value currently in the field. The EDITING phrase is part of the UPDATE statement; it displays information on the field as the user updates the record, and then reads each of the keystrokes entered (READKEY) and applies those keystrokes (APPLY LASTKEY).

```
r-frfld.p
FOR EACH Customer:
  WITH 1 DOWN 1 COLUMN CENTERED EDITING:
  DISPLAY "You are editing field:" FRAME-FIELD SKIP
  "of file:" FRAME-FILE SKIP
  "Its value is:" FRAME-VALUE FORMAT "x(20)"
  WITH FRAME a ROW 15 NO-LABELS CENTERED.
  READKEY.
  APPLY LASTKEY.
  END. /* EDITING */
END.
```

**Notes**

- If the current or last input field is an array, FRAME-FIELD returns the name of the field but does not indicate the array element that the input field represents. To display the array element, use the FRAME-INDEX function.
- If the cursor was not in an enabled input field when the last input statement ended, FRAME-FIELD returns an empty string.

**See also** FRAME-FILE function, FRAME-INDEX function, FRAME-VALUE function, PROGRAM-NAME function

---

**FRAME-FILE function**

Returns the name of the database table that contains the field the cursor is in. The FRAME-FILE function is useful if you want to provide users with context-sensitive help.

**Note:** Does not apply to SpeedScript programming.
FRAME-INDEX function

Syntax

| FRAME-INDEX |

Example

This procedure updates fields from the Order table and the Customer table. It uses the FRAME-FILE function to tell you which table contains the field being updated.

\[ \text{r-frfile.p} \]

```
FOR EACH Customer, EACH Order OF Customer:
    DISPLAY Order.OrderNum WITH CENTERED ROW 2 FRAME onum.
    UPDATE
        Customer.CustNum AT 5 Order.CustNum AT 30 SKIP
        Customer.Name AT 5
        Customer.City AT 5
        Customer.State AT 5
        Customer.PostalCode AT 5
    WITH ROW 8 CENTERED 1 DOWN NO-LABELS EDITING:
    MESSAGE "The field" FRAME-FIELD "is from the" FRAME-FILE "file".
    READKEY.
    APPLY LASTKEY.
END. /* EDITING */
END.
```

Notes

- FRAME-FILE returns a null string if the frame field being entered is not associated with a database field.
- If the cursor is not in an enabled input field when the last input statement ends, FRAME-FILE returns a null string.
- The FRAME-FILE value is set to blanks at the next PAUSE statement, at the next READKEY statement, or when the AVM pauses automatically.

See also

FRAME-FIELD function, FRAME-VALUE function, PROGRAM-NAME function

FRAME-INDEX function

During a data entry statement, returns the subscript of the array element of the input field that the cursor is in as an INTEGER value. At other times, returns the subscript of the array element the cursor was in.

The FRAME-INDEX function is particularly useful if you want to provide the user with help for the input array element being edited.

Note: Does not apply to SpeedScript programming.

Syntax

| FRAME-INDEX |

Example

In this example, the FRAME-INDEX function uses the cursor position to determine which option you have chosen:
The FRAME-LINE function returns an INTEGER value that represents the current logical line number in a down frame.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
FRAME-LINE [ ( frame ) ]
```

**frame**

The frame name that you are trying to determine a line number for. If you do not supply a frame name, the FRAME-LINE function uses the default frame for the block that contains the FRAME-LINE function. If the FRAME-LINE function is in a DO block, the function uses the default frame scoped to the block that contains the DO block.

---

**r-frindx.p**

```
DEFINE VARIABLE menu AS CHARACTER NO-UNDO EXTENT 3.

DO WHILE TRUE:
  DISPLAY
    "1. Display Customer Data" @ menu[1] SKIP
    "2. Display Order Data" @ menu[2] SKIP
    "3. Exit" @ menu[3] SKIP
  WITH FRAME choices NO-LABELS.
  CHOOSE FIELD menu AUTO-RETURN WITH FRAME choices
    TITLE "Demonstration Menu" WITH CENTERED ROW 10.
  HIDE FRAME choices.
  IF FRAME-INDEX EQ 1 THEN
    MESSAGE "You picked option 1."
  ELSE IF FRAME-INDEX EQ 2 THEN
    MESSAGE "You picked option 2."
  ELSE IF FRAME-INDEX EQ 3 THEN LEAVE.
END.
```
Example

This procedure lists Customers and allows the user to delete Customers one at a time. When the user presses GET to delete a Customer, the procedure displays an overlay frame below the last Customer displayed. The overlay frame prompts “Do you want to delete this customer?” The user answers yes or no. The AVM calculates the position of the overlay frame from the upper-right corner of the frame and the current line within the frame. That is, FRAME-ROW + 3 + FRAME-LINE gives the position of the current line in the frame, taking into account the three lines for the frame box and the labels. The prompt is placed five lines below the current line.

```
DEFINE VARIABLE ans AS LOGICAL NO-UNDO
   LABEL "Do you want to delete this customer?".

IF KBLABEL("GET") = "GET" THEN ON F3 GET.

STATUS INPUT "Enter data, or use the " + KBLABEL("get")
   + " key to delete the customer".

get-cust:
   FOR EACH Customer WITH 10 DOWN:
      UPDATE Customer.CustNum Customer.Name Customer.CreditLimit EDITING:
         READKEY.
         IF KEYFUNCTION(lastkey) = "get" THEN DO:
            UPDATE ans WITH ROW FRAME-ROW + 3 + FRAME-LINE + 5
            COLUMN 10 SIDE-LABELS OVERLAY FRAME del-frame.
            IF ans THEN DO:
               DELETE Customer.
               NEXT get-cust.
         END.
      END.
   END.
APPLY LASTKEY.
END.
END
```

Notes

- If there is a down pending for a frame, the FRAME-LINE function returns a value equal to FRAME-LINE + 1.
- The FRAME-LINE function counts an underline row as a logical line. A logical line corresponds to one iteration in a down frame and can contain more than one physical line.
- The FRAME-LINE function returns a value of 0 if the frame is not in view when the function is evaluated.

See also Frame phrase, FRAME-COL function, FRAME-DOWN function, FRAME-ROW function

FRAME-NAME function

Returns the name of the frame that the cursor is in to a field that is enabled for input.

Note:  Does not apply to SpeedScript programming.

Syntax

```
FRAME-NAME
```
Example

This procedure displays Customer information in one frame, then displays Order information for the Customer in a second frame. Use the FRAME-NAME function to display the name of the frame the cursor is in.

```
r-frname.p

FOR EACH Customer, EACH Order OF Customer:
   DISPLAY Order.OrderNum WITH CENTERED ROW 2 FRAME onum.
   UPDATE Customer.CustNum AT 5 Customer.Name AT 30 SKIP
      WITH FRAME custfrm WITH CENTERED 1 DOWN EDITING:
         DISPLAY " You are currently editing a frame called " FRAME-NAME
            WITH FRAME d1 WITH 1 DOWN CENTERED.
         READKEY.
         APPLY LASTKEY.
         IF LASTKEY = KEYCODE("RETURN") THEN
            MESSAGE " Press the space bar to edit order shipdate".
         END. /* Editing */
      HIDE FRAME custfrm.
      HIDE FRAME d1.
   UPDATE Order.ShipDate AT 5
      WITH FRAME orderfrm WITH CENTERED 1 DOWN EDITING:
         DISPLAY " Now you are editing a frame called" FRAME-NAME
            WITH FRAME d2 WITH 1 DOWN CENTERED.
         READKEY.
         APPLY LASTKEY.
      END.
      HIDE FRAME orderfrm.
      HIDE FRAME d2.
END.
```

Notes

- The FRAME-NAME function returns an empty string for a frame that has not been named (the default frame). It also returns an empty string if the cursor is in a field that is not enabled for input.

- When using the FRAME-NAME function, you must place it logically following the Frame phrase where it is named.

- FRAME-NAME is especially useful for context-sensitive help.

See also

Frame phrase, PROGRAM-NAME function

FRAME-ROW function

Returns a DECIMAL value that represents the row position of the upper-left corner of a frame within its window.

Note:  
Does not apply to SpeedScript programming.

Syntax

```
FRAME-ROW [ ( frame ) ]
```

frame

The name of the frame whose row position you are trying to determine. If you do not supply a frame name, the FRAME-ROW function uses the default frame for the block that
contains the FRAME-ROW function. If the FRAME-ROW function is in a DO block, the function uses the default frame scoped to the block that contains the DO block.

**Example**
This procedure displays Customer information in one frame, then displays Order information for the Customer in a second frame that overlays the first. FRAME-ROW and FRAME-COL control the placement of the overlay frame. FRAME-ROW places the overlay frame on the eighth row of the first frame. FRAME-COL places the overlay frame on the first column of the first frame.

```plaintext
r-frrow.p

FOR EACH Customer NO-LOCK:
    DISPLAY Customer WITH FRAME cust-frame 2 COLUMNS
    TITLE "CUSTOMER INFORMATION".
FOR EACH Order OF Customer NO-LOCK:
    DISPLAY Order.OrderNum Order.OrderDate Order.ShipDate
    Order.PromiseDate Order.Carrier Order.Instruction Order.PO
    WITH 2 COLUMNS 1 DOWN OVERLAY TITLE "CUSTOMER’S ORDERS"
    FRAME-ROW(cust-frame) + 8 COLUMN FRAME-COL(cust-frame) + 1.
END.
END.
```

**Note**
To convert the decimal value returned by FRAME-ROW to an integer value, use the INTEGER function.

**See also**
Frame phrase, FRAME-COL function, FRAME-DOWN function, FRAME-LINE function, INTEGER function

**FRAME-VALUE function**

During a data entry statement, returns the (character string) value of the input field that the cursor is in to the current input field. At other times, returns the (character string) value of the input field the cursor was last in.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
FRAME-VALUE
```

**Example**
When the user presses **END-ERROR** while running this procedure, the procedure displays the name and value of the field the user was updating, along with the name of the table that contains that field.
FRAME-VALUE statement

Stores the value of an expression in a frame field during a data entry statement.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
FRAME-VALUE = expression
```

*expression*

A constant, field name, variable name or expression whose value you want to store in a frame field. If no frame is active when the AVM runs this statement, the AVM returns an error message. Otherwise, if the frame is in view, the AVM redisplays the field.

The data type of the *expression* must be the same as the data type of the frame field in which you are storing that expression. However, if the data type of *expression* is character, the AVM stores characters in the frame field regardless of the data type of that frame field, truncating characters if necessary.

---

**Notes**

- If the cursor is not in an enabled input field when the last input statement ends, FRAME-VALUE returns a null string.
- FRAME-VALUE is set to blanks at the next pause (done by a PAUSE statement or automatically by the AVM) or at the next READKEY statement.
- FRAME-VALUE returns strings. If you use FRAME-VALUE to return a number, you must convert it prior to numeric comparisons. For example:

```
FIND Customer WHERE Customer.CustNum = INTEGER(FRAME-VALUE)
```
The `FRAME-VALUE` statement can pass information from an `app1help.p` procedure to the calling procedure. For example, if the user enters a value into a field called `help-field`, you can pass that value back to the calling procedure with this statement:

```apl
FRAME-VALUE = INPUT help-field.
```

### Example

This procedure displays the word PROGRESS, the date, and a message instructing you to enter data or press the GET key to enter the Unknown value (?). You can update the information in the frame. If you press GET, the `r-frmval.p` procedure assigns the Unknown value (?) to a field with the `FRAME-VALUE` statement.

```apl
DEFINE VARIABLE txt AS CHARACTER NO-UNDO INITIAL "PROGRESS".
DEFINE VARIABLE tmpdate AS DATE NO-UNDO INITIAL TODAY.
IF KLABEL("GET") = "GET" THEN ON F3 GET.
STATUS INPUT "Enter data or use the " + KLABEL("GET")
 + " key to enter the unknown value (?)".
UPDATE txt tmpdate EDITING:
  READKEY.
  IF KEYFUNCTION(LASTKEY) = "GET" THEN DO:
    FRAME-VALUE = ?.
    NEXT.
    END.
    APPLY LASTKEY.
  END.
END.
```

### Note

For more information on frames, see *OpenEdge Getting Started: ABL Essentials*.

### See also

FRAME-FIELD function, FRAME-FILE function, FRAME-VALUE function

## FUNCTION statement

Defines or declares a prototype for a user-defined function, or declares a Web service operation. The following syntax boxes describe the syntax for each use of the statement, beginning with a user-defined function definition.

### Syntax

```apl
FUNCTION function-name [ RETURNS ] return-type [ PRIVATE ]
[ ( parameter [, parameter ] ... ) ] :
function-body
```

Use the following syntax to declare a user-defined function prototype that is defined later in the same procedure or that is defined in another external procedure:
FUNCTION statement

Use the following syntax to declare a Web service operation. For more information on declaring Web service operations, see *OpenEdge Development: Web Services*.

```plaintext
FUNCTION function-name [ RETURNS ] return-type
[ ( parameter , parameter ) ... ]
{ FORWARD
  | [ MAP [ TO ] actual-name ] IN proc-handle
  | IN SUPER
}
```

**function-name**

The name of the function. You must avoid ABL reserved keywords. For a list of ABL keywords, see the Keyword Index in this manual.

**[ RETURNS ] return-type**

Indicates the data type of the function return value. You can specify `return-type` as one of the following data types. For more information on each data type, see the Data types reference entry:

```plaintext
{ CHARACTER | COM-HANDLE | DATE | DATETIME | DATETIME-TZ | DECIMAL
  | HANDLE | INT64 | INTEGER | LOGICAL | LONGCHAR | MEMPTR | RAW
  | RECID | ROWID
  | [ CLASS ] object-type-name } [ EXTENT [ constant ] ]
```

**object-type-name**

Specifies the type name of an ABL or .NET class or interface. Specify an object type name using the syntax described in the Type-name syntax reference entry. With an appropriate USING statement, you can also specify a class or interface name alone, without the qualifying package or namespace.

**CLASS**

If the specified class or interface type name conflicts with an abbreviation of a built-in primitive type name, such as INT for INTEGER, you must specify the CLASS keyword.

For a class or interface return value, ABL returns an object reference associated with the class or interface, not a class instance itself. For more information on object references, see the Class-based object reference reference entry.
FUNCTION statement

EXTENT [ constant ]

Defines the return value as an array of data elements with the specified primitive or object type. This option can specify an array return value as either determinate (has a defined number of elements) or indeterminate (has an undefined number of elements). To define a determinate array return value, specify the EXTENT option with the constant argument. This optional argument is an integer value that represents the number of elements in the array. To define an indeterminate array return value, specify the EXTENT option without the constant argument.

An indeterminate array return value can be in one of two states: fixed or unfixed, meaning it either has a fixed dimension or it does not. An indeterminate array return value has an unfixed dimension when first defined. You can fix the dimension of an indeterminate array return value by:

- Setting the number of elements in the array return value using the EXTENT statement
- Assigning a determinate array to the indeterminate array value, fixing it to the dimension of the determinate array
- Passing array parameters to a procedure, user-defined function, or class-based method, so that the indeterminate array value is the target for the passing of a determinate array, fixing the indeterminate array to the dimension of the determinate array

Once fixed, ABL treats a fixed indeterminate array as a determinate array.

If you do not use the EXTENT option (or you specify constant as 0), the return value is not an array return value.

Note: If you invoke a function on an AppServer, the function cannot return a value as a LONGCHAR, MEMPTR, or CLASS.

PRIVATE

Indicates the following about the user-defined function:

- That it cannot be invoked from an external procedure—that is, from a procedure file external to the current procedure file.
- That the INTERNAL-ENTRIES attribute on the procedure that defines it does not provide its name (unless the procedure that defines it is the current procedure file).
- That the GET-SIGNATURE( ) method on the procedure that defines it does not provide its signature (unless the procedure that defines it is the current procedure file).

( parameter [, parameter ] ... )

Defines one or more parameters of the function.

For information on the parameter definition syntax, see the Parameter definition syntax reference entry.
**function-body**

The body of a function definition. Define **function-body** using the following syntax:

```
function-logic

[ catch-block [ catch-block ... ] ]
[ finally-block ]
END [ FUNCTION ] .
```

**function-logic**

The logic of the function. This logic can contain the ABL statements allowed within a procedure block, with the following differences:

- The RETURN ERROR statement returns the Unknown value (?) for the function, regardless of its return type, but does **not** raise ERROR in the caller.

- You cannot make direct or indirect reference to statements that block for input (namely, the CHOOSE, INSERT, PROMPT-FOR, READKEY, SET, UPDATE, and WAIT-FOR statements).

To return a function value of the data type specified by **return-type**, you can execute the **RETURN** statement to set a value of that data type to return at run time. If you omit the RETURN statement, the function returns the Unknown value (?), regardless of the data type specified by **return-type**.

If **return-type** is defined as a .NET array of mapped types (for example, "System.Byte[]"), you must return an object reference of the specified .NET array of mapped types in the RETURN statement. You cannot return an ABL array of a type that maps to the .NET array type (for example, INTEGER EXTENT) or the AVM raises a run-time error. If you do not execute any RETURN statement for **return-type** in the **function-logic**, the user-defined function returns the Unknown value (?) as its return value.

Each logic statement must end with a period.

**catch-block**

Specifies a CATCH statement that defines error handling code for one or more error types. A DO block does not have any default error handling. Therefore, a DO block must have error handling options specified such that it becomes an undoable block. Otherwise, ABL generates a compiler warning. For more information on **catch-block**, see the CATCH statement reference entry.

**finally-block**

Specifies a FINALLY statement that defines the processing that must occur after all other processing in the block occurs. For more information on **finally-block**, see the FINALLY statement reference entry.
FUNCTION statement

END [ FUNCTION ]

Specifies the end of the function body definition. You must end the function body
definition with the END statement.

FORWARD

Declares a prototype for a function in a procedure whose definition appears later in the
same procedure. You must declare a user-defined function prototype when the function
definition appears within the same procedure following the first use of the function. This
prototype must appear in the procedure before the first use of the function.

The FUNCTION statement with the FORWARD option must include the following
information on the function: the data type it returns, and the data type and mode (INPUT,
OUTPUT, or INPUT-OUTPUT) of each parameter.

If you declare a function prototype, reference it, and do not define it before the end of the
procedure, the compiler returns an error.

[ MAP [ TO ] actual-name ] IN proc-handle

Declares prototype for a function that resides in a procedure external to the declaring
procedure, with the following information:

- Optionally, that function-name (the second element in the FUNCTION statement)
is an alias (alternative name) for the function and that actual-name is the name that
appears in the function definition.

- The definition of the function resides in another external procedure specified by
proc-handle, which represents an expression that evaluates to a handle to the
procedure that defines the function. This procedure can be an active procedure in the
local context or a remote persistent procedure. For more information on remote
user-defined functions, see OpenEdge Application Server: Developing AppServer
Applications.

**Note:** The MAP option might simplify your code if it references two different
user-defined functions that have the same name but that reside in different
procedures.

A FUNCTION statement with the IN proc-handle option must include the following
information on the function: the data type it returns, and the data type and mode (INPUT,
OUTPUT, or INPUT-OUTPUT) of each parameter.

IN SUPER

Declares a prototype for a function whose definition resides in a super procedure.

A FUNCTION statement with the IN SUPER option must include the following
information on the function: the data type it returns, and the data type and mode (INPUT,
OUTPUT, or INPUT-OUTPUT) of each parameter.

operationName

The name of a Web service operation specified in a WSDL file.
**Examples**

The first example, r-udf1.p, defines and references the user-defined function doubler(), which accepts an integer and returns the integer multiplied by two:

**r-udf1.p**

```plaintext
/* r-udf1.p */
/* Defines and references a user-defined function */

/* Define doubler() */
FUNCTION doubler RETURNS INTEGER (INPUT parm1 AS INTEGER):
  RETURN (2 * parm1).
END FUNCTION.

/* Reference doubler() */
DISPLAY "doubler(0)=" doubler(0) SKIP
  "doubler(1)=" doubler(1) skip
  "doubler(2)=" doubler(2) skip.
```

The second example, r-udf2.p, declares a prototype for, references, and defines doubler():

**r-udf2.p**

```plaintext
/* r-udf2.p */
/* Forward-declares, references, and defines a user-defined function */

/* Forward declare doubler() */
FUNCTION doubler RETURNS INTEGER (INPUT parm1 AS INTEGER) FORWARD.

/* Reference doubler() */
DISPLAY "doubler(0)=" doubler(0).
DISPLAY "doubler(1)=" doubler(1).
DISPLAY "doubler(2)=" doubler(2).

/* Define doubler() */
FUNCTION doubler RETURNS INTEGER (INPUT parm1 AS INTEGER):
  RETURN (2 * parm1).
END FUNCTION.
```

The third example consists of two procedures, r-udf3.p and r-udfdef.p. The example illustrates defining a prototype for user-defined function that is defined in an external procedure.

The procedure, r-udf3.p, declares the prototype for doubler(), runs r-udfdef.p persistently, invokes doubler(), and deletes the persistent procedure:
The second procedure, r-udfdef.p, defines doubler:

```
r-udfdef.p

/* r-udfdef.p */
/* Defines user-defined function doubler() */

FUNCTION doubler RETURNS INTEGER (INPUT parm1 AS INTEGER):
    RETURN (2 * parm1).
END FUNCTION.
```

To start the third example, run r-udf3.p in the Procedure Editor.

In the fourth example, r-fctrl2.p, the user-defined function fact() implements the factorial function, common in probability and statistics, and commonly notated “!” (6! = 6 x 5 x 4 x 3 x 2 x 1; 100! = 100 x 99 x 98 x ... x 3 x 2 x 1):

```
r-fctrl2.p

/* r-fctrl2.p */
/* Demonstrates user-defined function fact() */

DEFINE VARIABLE inp AS INTEGER LABEL "Input Value".

FUNCTION fact RETURNS INTEGER (INPUT val AS INTEGER):
    IF val LT 0 THEN RETURN 0.
    IF val LE 1 THEN RETURN 1.
    RETURN val * fact(val - 1).
END.

REPEAT:
    UPDATE inp WITH TITLE "Factorials".
    DISPLAY fact(inp) LABEL "Factorial".
END.
```

Notes
- You can terminate a FUNCTION statement with either a period (.) or a colon (:), but typically use a colon (:) for a function definition and a period (.) for a function prototype or to declare a Web service operation.
• Before you reference a user-defined function within a procedure, you must define it, declare its prototype, declare it as external (by using FUNCTION statement’s IN option), or define it.

• You cannot define shared objects, work tables, temp-tables, or ProDataSet objects within a user-defined function.

• ABL implements scalar and array parameters of user-defined functions as NO-UNDO variables.

• A reference to a user-defined function must match the declared prototype or definition with respect to the return type, and with respect to the number, type, and mode of the parameters.

• When an ABL predicate (such as a WHERE clause) contains a user-defined function, the AVM evaluates the function once—when it opens the query or enters the FOR EACH block.

• When the AVM encounters a user-defined function declared externally that references a user-defined function declared externally that references a user-defined function declared externally, etc., the AVM tolerates up to 64 levels of indirection. At the 65th level, the AVM raises an error and returns the Unknown value (?)

• If a user-defined function has one or more buffer parameters and its definition resides in another procedure, the referencing procedure and the defining procedure must reside on the same machine. If a user-defined function does not have buffer parameters, the invoking procedure and the defining procedure can reside on different machines.

• When you invoke a user-defined function (or a built-in function), you do not need to assign the function’s return value to a variable. That is, you can invoke a user-defined function as a statement, ignoring the return value. You might use this technique with a function that performs some action on a persistent object, such as a shared variable, when you want the action to occur and do not need to check the return value. For example:

  doubler (my-shared-variable).

• When you invoke a user-defined function, you may pass a TABLE, TABLE-HANDLE, DATASET, or DATASET-HANDLE parameter by value, by reference, or by binding using the BY-VALUE, BY-REFERENCE, or BIND keyword, respectively. For example:

  myfunc (OUTPUT TABLE tt BY-REFERENCE).

For more information about passing these parameters by value, by reference, or by binding, see the Parameter passing syntax reference entry.

• To return an error to the caller from a user-defined function, you can:

  – Migrate from using a user-defined function defined within a procedure to using a method defined within a class.
FUNCTION statement

- Use the ROUTINE-LEVEL ON ERROR UNDO, THROW statement in conjunction with the THROW option of the UNDO statement or the ON ERROR phrase in the user-defined function block.

- Use the THROW option of the UNDO statement or the ON ERROR phrase from a CATCH block (CATCH statement) within the user-defined function block.

- Invoke the STOP statement to raise the STOP condition in the caller.

See also

DYNAMIC-FUNCTION function, METHOD statement, Parameter definition syntax, PROCEDURE statement, RETURN statement
GATEWAYS function

The GATEWAYS function has been replaced by the DATASERVERS function, which is exactly equivalent.

This function is supported only for backward compatibility.

**Note:** Does not apply to SpeedScript programming.

### Syntax

```
GATEWAYS
```

### GE or >= operator

Returns a TRUE value if the first of two expressions is greater than or equal to the second expression.

#### Syntax

```
expression { GE | >= } expression
```

#### expression

A constant, field name, variable name, or any combination of these. The expressions on either side of the GE or >= must be of the same data type, although one might be integer and the other decimal.

#### Example

This procedure displays item information for those items whose OnHand value is greater than or equal to 120:

```
r-ge.p
```

```
FOR EACH Item NO-LOCK WHERE Item.OnHand >= 120:
END.
```

### Notes

- By default, the AVM uses the collation rules you specify to compare characters and sort records. The collation rules specified with the Collation Table (-cpcoll) startup parameter take precedence over a collation specified for any database the AVM accesses during the session, except when the AVM uses or modifies pre-existing indexes. If you do not specify a collation with the -cpcoll startup parameter, the AVM uses the language collation rules defined for the first database on the command line. If you do not specify a database on the command line, the AVM uses the collation rules with the default name "basic" (which might or might not exist in the convmap.cp file).

- If either of the expressions is the Unknown value (?), then the result is the Unknown value (?); if both expressions are the Unknown value (?), then the result is TRUE.

- You can compare character strings with GE. Most character comparisons are case insensitive in ABL. That is, upper-case and lower-case characters have the same sort
value. However, it is possible to define fields and variables as case sensitive (although it is not advised, unless strict ANSI SQL adherence is required). If either expression is a field or variable defined as case sensitive, the comparison is case sensitive and “Smith” does not equal “smith”.

- Characters are converted to their sort code values for comparison. Using the default case-sensitive collation table, all uppercase letters sort before all lowercase letters (for example, a is greater than Z, but less than b.) Note also that in character code uppercase A is less than [ , \ , ^ , _ , and ‘ , but lowercase a is greater than these.

- You cannot compare data of different DATE, DATETIME, and DATETIME-TZ data types to each other using GE. You must first convert different date and datatime data types to the same data type before doing a comparison between them.

- You can use GE to compare a LONGCHAR variable to another LONGCHAR or CHARACTER variable. The variable values are converted to -cpinternal for comparison and must convert without error, or the AVM raises a run-time error.

- You cannot use GE to compare one CLOB field to another.

### GENERATE-PBE-KEY function

Generates a password-based encryption key, based on the PKCS#5/RFC 2898 standard, and returns the key as a RAW value.

#### Syntax

```
GENERATE-PBE-KEY( password [, salt ] )
```

**password**

The password (a binary value) to use in generating the encryption key. This value may be of type CHARACTER, LONGCHAR, RAW, or MEMPTR. If the password contains a CHARACTER or LONGCHAR value, the AVM converts it to UTF-8 (which ensures a consistent value regardless of code page settings) before using it to generate the encryption key. To avoid this automatic conversion, specify a RAW or MEMPTR value. If you specify the Unknown value (?), the result is the Unknown value (?).

**salt**

An optional RAW expression that evaluates to the salt value (a random series of 8 bytes) to use in generating the encryption key. If you specify the Unknown value (?), the current value of the ENCRYPTION-SALT attribute is used. If no salt value is specified in the ENCRYPTION-SALT attribute, no salt value is used.

You can also use the GENERATE-PBE-SALT function to generate a salt value, which can help to ensure that the password key value is unique.

If specified, this salt value is combined with the password value and hashed some number of times to generate a password-based encryption key (using the algorithm specified by the PBE-HASH-ALGORITHM attribute and the number of iterations specified by the PBE-KEY-ROUNDS attribute).

#### Notes

- You are responsible for generating, storing, and transporting these values.
• The size of the generated encryption key is determined by the cryptographic algorithm specified by the SYMMETRIC-ENCRYPTION-ALGORITHM attribute.

• Before invoking this function, be sure to set the PBE-HASH-ALGORITHM attribute to the name of the hash algorithm to use.

• If you call this function multiple times with the same password string, hash algorithm, number of iterations, and salt value, the same binary key is generated each time.

See also GENERATE-PBE-SALT function, GENERATE-RANDOM-KEY function, MD5-DIGEST function, SHA1-DIGEST function, SECURITY-POLICY system handle

---

### GENERATE-PBE-SALT function

Generates a random salt value (a series of 8 bytes) to use in generating an encryption key, and returns the salt value as a RAW value. Using a salt value can help to ensure that a password key value is unique.

#### Syntax

```plaintext
GENERATE-PBE-SALT
```

#### Notes

• This salt value is combined with a password value and hashed some number of times to generate a password-based encryption key (using the algorithm specified by the PBE-HASH-ALGORITHM attribute and the number of iterations specified by the PBE-KEY-ROUNDS attribute).

• You are responsible for generating, storing, and transporting this value.

See also GENERATE-PBE-KEY function, MD5-DIGEST function, SHA1-DIGEST function, SECURITY-POLICY system handle

---

### GENERATE-RANDOM-KEY function

Generates a pseudorandom (rather than a truly random) series of bytes to use as an encryption key, and returns the key as a RAW value.

#### Syntax

```plaintext
GENERATE-RANDOM-KEY
```

#### Notes

• You are responsible for generating, storing, and transporting this value.

• The size of the generated encryption key is determined by the cryptographic algorithm specified by the SYMMETRIC-ENCRYPTION-ALGORITHM attribute.

• The Alternate Random Number Generator (-rand) startup parameter setting has no effect on this function.

See also GENERATE-PBE-KEY function, SECURITY-POLICY system handle
**GENERATE-UUID function**

Generates a universally unique identifier (UUID), as a 16-byte RAW value.

**Syntax**

```plaintext
GENERATE-UUID
```

**Example**

The following code fragment illustrates how to use the GENERATE-UUID function:

```plaintext
DEFINE VARIABLE MyUUID AS RAW NO-UNDO.
DEFINE VARIABLE Base64UUID AS CHARACTER NO-UNDO.
ASSIGN
  MyUUID    = GENERATE-UUID
  Base64UUID = BASE64-ENCODEx(MyUUID).
```

You can use the GENERATE-UUID function with the BASE64-ENCODE function to generate a UUID and convert it to use in a Base64 character index. You can also remove the two trailing Base64 pad characters to reduce the size of the UUID. For example:

```plaintext
SUBSTRING(BASE64-ENCODE(GENERATE-UUID), 1, 22)
```

**See also**

BASE64-ENCODE function, GUID function

---

**GET statement**

Returns one record for a previously opened query.

**Syntax**

```plaintext
GET { FIRST | NEXT | PREV | LAST | CURRENT } query
  [ SHARE-LOCK | EXCLUSIVE-LOCK | NO-LOCK ]
  [ NO-WAIT ]
```

**FIRST query**

Finds the first record associated with the query. The query must have been previously opened in an OPEN QUERY statement. The order of the records is determined by the options specified in the Record phrase of the OPEN QUERY statement.

**NEXT query**

Returns the first or next record associated with the query. The query must have been previously opened in an OPEN QUERY statement. The order of the records is determined by the options specified in the OPEN QUERY statement of the Record phrase.
PREV query

Returns the preceding or last record associated with the query. The query must have been previously opened in an OPEN QUERY statement. The order of the records is determined by the options specified in the OPEN QUERY statement of the Record phrase.

LAST query

Returns the last record associated with the query. The query must have been previously opened in an OPEN QUERY statement. The order of the records is determined by the options specified in the OPEN QUERY of the Record phrase.

CURRENT query

Refetches the current record or records associated with the query. The query must have been previously opened in an OPEN QUERY statement. If the query is a join, the AVM returns the current record for all tables in the join.

SHARE-LOCK

Specifies that the record is share locked. Overrides the default locking of the OPEN QUERY statement. This applies to all buffers in a join.

EXCLUSIVE-LOCK

Specifies that the record is exclusively locked. Overrides the default locking of the OPEN QUERY statement. This applies to all buffers in a join.

NO-LOCK

Specifies that no lock is applied to the record. Overrides the default locking of the OPEN QUERY statement. This applies to all buffers in a join.

NO-WAIT

Specifies that the GET statement returns immediately if the record cannot be accessed because it is locked by another user. If you do not use the NO-WAIT option, the GET statement waits until the record can be accessed. This applies to all buffers in a join. If you specify NO-WAIT and the record is locked by another user, the record is returned to you with NO-LOCK and the LOCKED function returns TRUE for the record.

Example

This procedure uses the GET statement to find Customer orders:

r-getord.p

```
DEFINE QUERY cust-order FOR Customer, Order.
OPEN QUERY cust-order FOR EACH Customer, EACH Order OF Customer.
GET FIRST cust-order.
DO WHILE AVAILABLE Customer:
  DISPLAY Customer.CustNum Customer.Name
      WITH FRAME cust-info.
  DISPLAY Order WITH FRAME order-info SIDE-LABELS.
  PAUSE.
  GET NEXT cust-order.
END.
```
In the example, the GET FIRST statement fetches the first Customer record and the first Order record for that Customer. The GET NEXT statement fetches the next Order record for the Customer. If no more Order records are found for the current Customer, then the GET NEXT statement fetches the next Customer and the first Order record for that Customer. If a Customer has no Orders, the GET statement skips that Customer.

### Notes

- The query must be opened with the OPEN QUERY statement before any records are fetched.
- A query that references more than one buffer defines a join. Each GET statement returns one set of records.
- If you execute a GET NEXT statement after the last record of the query has been fetched or you execute a GET PREV statement after the first record of the query has been fetched, the ERROR condition is not raised. However, you can use the AVAILABLE function to test whether a record was returned for the query fetch. You can also use the QUERY-OFF-END function to determine if the query is positioned at the end of its result list.
- If the query is positioned before the first record, GET NEXT acts the same as a GET FIRST; similarly, if the query is positioned beyond the last record, GET PREV acts the same as GET LAST.
- The GET LAST statement can be slow unless the AVM has performed a presort or already returned the last record that satisfies the query, or you specify USE-INDEX for the query (or the query happens to only use one index). Also, GET LAST might be slow if the query involves an outer join.
- If you do not specify a lock type, the AVM uses the lock type specified in the OPEN QUERY statement. If no lock type is specified in either the GET or OPEN QUERY statement, then the default ABL locking rules apply.
- If a GET CURRENT statement fails because of a lock conflict, the AVM rereads the record with a NO-LOCK status.
- When a GET statement executes, any FIND triggers defined for the tables are executed.
- FIND triggers do not execute for a GET CURRENT statement.
- To upgrade the lock on only one table in a join, use the FIND CURRENT statement.
- A query that includes a BREAK BY phrase becomes a FORWARD-ONLY query. In this case you cannot use the GET FIRST, GET LAST, or GET PREV statements. If you do, the AVM raises ERROR.

AVAILABLE function, CLOSE QUERY statement, CURRENT-CHANGED function, CURRENT-RESULT-ROW function, DEFINE QUERY statement, FIND statement, FOR statement, LOCKED function, NUM-RESULTS function, OPEN QUERY statement, QUERY-OFF-END function, REPOSITION statement
**GET-BITS function**

Interprets one or more consecutive bits in an integer variable or field as an ABL integer value and returns that value.

**Syntax**

```
GET-BITS( source, position, numbits )
```

*source*

An ABL integer variable.

*position*

A variable or expression that returns an integer. This parameter designates the position of the lowest-order bit of the bits that are to be interpreted as an integer. Bits are numbered from 1 through the length of an integer; with 1 being the low-order bit. If `position` is greater than the length of an integer, the AVM returns the Unknown value (?). If `position` is less than 1, the AVM generates a run-time error.

*numbits*

The number of bits to examine when generating the return value. If `position` plus `numbits` is greater than the length of an integer plus 1, the AVM generates a run-time error.

**Note**

This function can return a value greater than 32 bits if `source` is an INT64.

**See also**

PUT-BITS statement

---

**GET-BYTE function**

Returns the unsigned 1 byte value at the specified memory location as an INTEGER value.

**Syntax**

```
GET-BYTE( source, position )
```

*source*

A function or variable that returns a RAW or MEMPTR value. If `source` is the Unknown value (?), GET-BYTE returns the Unknown value (?).

*position*

An integer value greater than 0 that indicates the byte position where you want to find the information. If `position` is greater than the length of `source`, the AVM returns the Unknown value (?). If `position` is less than 1, the AVM generates a run-time error.

**Examples**

In this example, the RAW function goes to the Customer field in the non-OpenEdge database. The GET-BYTE function accesses the first byte and stores the integer value of that byte in the variable ix. The procedure then tests the value, if the integer value is 83 (the character code value for S), the AVM displays the Customer Name.
The next procedure sets up a MEMPTR region with a character string and uses the GET-BYTE function to display the character code value of each character in the string:

```
r-mptget.p

DEFINE VARIABLE mptr AS MEMPTR NO-UNDO.
DEFINE VARIABLE cnt AS INTEGER NO-UNDO.

ASSIGN
SET-SIZE(mptr) = LENGTH("DANIEL") + 1
PUT-STRING(mptr, 1) = "DANIEL".

REPEAT cnt = 1 TO LENGTH("DANIEL"):
   DISPLAY GET-BYTE(mptr, cnt).
END.
```

```
r-rawget.p

/* You must connect to a non-OpenEdge database to run this procedure */
DEFINE VARIABLE ix AS INTEGER NO-UNDO.

FOR EACH Customer:
   ix = GET-BYTE(RAW(Customer.Name), 1).
   IF ix = 83 THEN
      DISPLAY Customer.Name.
   END.
```

Notes

- For more information on using the MEMPTR and RAW data types, see *OpenEdge Development: Programming Interfaces*.
- You can use the alternative keyword GETBYTE instead of GET-BYTE.

See also

LENGTH function, PUT-BYTE statement, RAW function, RAW statement, SET-SIZE statement

**GET-BYTE-ORDER function**

Returns an INTEGER value indicating the byte order setting of a MEMPTR variable. This will be either the value provided by the last execution of SET-BYTE-ORDER with this MEMPTR variable, or HOST-BYTE-ORDER if SET-BYTE-ORDER has not been executed.

**Syntax**

```
GET-BYTE-ORDER( memptr )
```

`memptr`

An expression that returns a MEMPTR.

**Note**

GET-BYTE-ORDER never affects data currently in the MEMPTR. That is, it does not actually re-order the data.

**See also**

SET-BYTE-ORDER statement
**GET-BYTES function**

Returns the specified number of bytes, from the specified location, into a RAW or MEMPTR variable.

**Syntax**

```
GET-BYTES( source, position, numbytes )
```

**source**

An expression that evaluates to a RAW or MEMPTR value indicating the source location. If `source` is the Unknown value (?), GET-BYTES returns the Unknown value (?).

**position**

An integer value greater than 0 indicating the byte position of the first byte to get. If `position` is greater than the length of `source`, the AVM returns the Unknown value (?). If `position` is less than 1, the AVM generates a run-time error.

**numbytes**

An integer value greater than 0 indicating how many bytes to return as a RAW value. If `position` plus `numbytes` is greater than the size of `source`, the AVM returns the Unknown value (?).

If the variable that accepts the returned data is a RAW variable and `numbytes` is greater than its length but less than or equal to 32K, the AVM increases the size of the variable to `numbytes`.

If either the source location, `source`, or the variable that accepts the returned data is a RAW value, and `numbytes` is greater than 32K, the AVM generates a run-time error.

If the variable that accepts the returned data is a MEMPTR variable and `numbytes` is greater than its length, the AVM generates a run-time error.

**See also**

PUT-BYTES statement

---

**GET-CODEPAGE function**

The GET-CODEPAGE function returns the code page of a LONGCHAR variable or CLOB field.

**Syntax**

```
GET-CODEPAGE ( large-char-object )
```

**large-char-object**

The name of a LONGCHAR variable or CLOB field. If the specified LONGCHAR is empty and the code page was not fixed using the FIX-CODEPAGE statement, the AVM returns the Unknown value (?).

**See also**

FIX-CODEPAGE statement, IS-CODEPAGE-FIXED function
**GET-CODEPAGES function**

The GET-CODEPAGES function returns a comma-delimited list of the code pages listed in convmap.cp or specified by the Conversion Map (-convmap) startup parameter for the current ABL session.

**Syntax**

```
GET-CODEPAGES
```

**Example**

This procedure displays a list of the code pages available in memory for the current ABL session and the collations available for each code page:

```
r-get.p
```

```plaintext
DEFINE VARIABLE code-page-list AS CHARACTER NO-UNDO.
DEFINE VARIABLE collation-list AS CHARACTER NO-UNDO.
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE jx  AS INTEGER NO-UNDO.

code-page-list = GET-CODEPAGES.
REPEAT ix = 1 TO NUM-ENTRIES(code-page-list):
    DISPLAY ENTRY(ix, code-page-list) FORMAT "x(19)" COLUMN-LABEL "Code Page"
        WITH DOWN FRAME a.
    collation-list = GET-COLLATIONS(ENTRY(ix, code-page-list)).
    REPEAT jx = 1 TO NUM-ENTRIES(collation-list):
        DISPLAY ENTRY(jx, collation-list) FORMAT "x(19)"
            COLUMN-LABEL "Collation"
            WITH DOWN FRAME a.
        END.
    END.
END.
```

**See also**

GET-COLLATIONS function

**GET-COLLATION function**

The GET-COLLATION function returns the collation name for a CLOB field.

**Syntax**

```
GET-COLLATION ( clob-field )
```

**clob-field**

A CLOB field name.

**GET-COLLATIONS function**

The GET-COLLATIONS function returns a comma-delimited list of the collations either listed in convmap.cp or specified by the Conversion Map (-convmap) startup parameter for the specified code page.
GET-COLLATIONS ( codepage )

codepage

A code page name. If there are no collations for the specified code page, the AVM returns the Unknown value (\?).

Example

This procedure displays a list of the code pages available in memory for the current ABL session and the collations available for each code page:

r-get.p

```
DEFINE VARIABLE code-page-list AS CHARACTER NO-UNDO.
DEFINE VARIABLE collation-list AS CHARACTER NO-UNDO.
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE jx AS INTEGER NO-UNDO.

code-page-list = GET-CODEPAGES.

REPEAT ix = 1 TO NUM-ENTRIES(code-page-list):
   DISPLAY ENTRY(ix, code-page-list) FORMAT "x(19)" COLUMN-LABEL "Code Page"
   WITH DOWN FRAME a.
   collation-list = GET-COLLATIONS(ENTRY(ix, code-page-list)).

REPEAT jx = 1 TO NUM-ENTRIES(collation-list):
   DISPLAY ENTRY(jx, collation-list) FORMAT "x(19)"
   COLUMN-LABEL "Collation"
   WITH DOWN FRAME a.
   DOWN WITH FRAME a.
END.
END.
```

See also

GET-CODEPAGES function

GET-DOUBLE function

Returns the 8-byte floating-point value at the specified memory location as a DECIMAL value.

Syntax

GET-DOUBLE ( source , position )

source

A function or variable that returns a RAW or MEMPTR value. If source is the Unknown value (\?), GET-DOUBLE returns the Unknown value (\?).

position

An integer value greater than 0 that indicates the byte position where you want to find the information. If position is greater than the length of source, the AVM returns the Unknown value (\?). If position is less than 1, the AVM generates a run-time error.

Examples

For examples of how to use the GET-DOUBLE function, see the GET-BYTE function reference entry.
GET-FLOAT function

Notes

- This function supports byte-swapping only if source is a MEMPTR data type. The
function will first examine the byte-order setting of the MEMPTR and then swap the
bytes appropriately before interpreting them. The AVM does not swap the bytes in the
MEMPTR’s memory, but does the byte-swap as it creates the return value.

- For more information on using the MEMPTR and RAW data types, see OpenEdge
Development: Programming Interfaces.

See also LENGTH function, PUT-DOUBLE statement, RAW function, RAW statement, SET-SIZE
statement

GET-FLOAT function

Returns the 4-byte floating-point value at the specified memory location as a DECIMAL value.

Syntax

GET-FLOAT ( source , position )

source

A function or variable that returns a RAW or MEMPTR value. If source is the Unknown
value (?), GET-FLOAT returns the Unknown value (?).

position

An integer value greater than 0 that indicates the byte position where you want to find the
information. If position is greater than the length of source, the AVM returns the
Unknown value (?). If position is less than 1, the AVM generates a run-time error.

Examples

For examples of how to use the GET-FLOAT function, see the GET-BYTE function reference
entry.

Notes

- This function supports byte-swapping only if source is a MEMPTR data type. The
function will first examine the byte-order setting of the MEMPTR and then swap the bytes
appropriately before interpreting them. The AVM does not swap the bytes in the
MEMPTR’s memory, but does the byte-swap as it creates the return value.

- For more information on using the MEMPTR and RAW data types, see OpenEdge
Development: Programming Interfaces.

See also LENGTH function, PUT-FLOAT statement, RAW function, RAW statement, SET-SIZE
statement

GET-INT64 function

Returns the signed 64-bit value at the specified memory location as an INT64 value.

Syntax

GET-INT64 ( source , position )
source

A function or variable that returns a RAW or MEMPTR value. If source is the Unknown value (??), GET-INT64 returns the Unknown value (??).

position

An integer value greater than 0 that indicates the byte position where you want to find the information. If position is greater than the length of source, the AVM returns the Unknown value (??). If position is less than 1, the AVM generates a run-time error.

Example

The following example demonstrates how to get values in and out of RAW and MEMPTR values:

r-getint64.p

```
DEFINE VARIABLE myint64 AS INT64 NO-UNDO INITIAL 7888999000.
DEFINE VARIABLE myint AS INTEGER NO-UNDO INITIAL 2345.
DEFINE VARIABLE myraw AS RAW NO-UNDO.
DEFINE VARIABLE result64 AS INT64 NO-UNDO.
DEFINE VARIABLE result1 AS INTEGER NO-UNDO.
DEFINE VARIABLE memep AS MEMPTR NO-UNDO.

ASSIGN
  PUT-LONG(myraw,1) = myint
  result1 = GET-LONG(myraw,1)
  PUT-INT64(myraw,1) = myint64
  result64 = GET-INT64(myraw,1).

MESSAGE "raw version " result1 result64.

ASSIGN
  result1 = ?
  result64 = ?
  SET-SIZE(mymem) = 40
  PUT-LONG(mymem,1) = myint
  result1 = GET-LONG(mymem,1)
  PUT-INT64(mymem,1) = myint64
  result64 = GET-INT64(mymem,1).

MESSAGE "memptr version " result1 result64.

result1 = get-int64(mymem,1) NO-ERROR.

MESSAGE "store getint64 in int gives" ERROR-STATUS:GET-MESSAGE(1).
MESSAGE "doing put-long of in64" myint64.

PUT-LONG(mymem,1) = myint64 NO-ERROR.

MESSAGE "storeint64 with put-long gives" ERROR-STATUS:GET-MESSAGE(1).
SET-SIZE(mymem) = 0.
```

See also

INT64 function, INTEGER function, PUT-INT64 statement, GET-LONG function
GET-KEY-VALUE statement

(Windows only)

Searches the current environment for a particular key and places its value into a particular data item.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
GET-KEY-VALUE SECTION section-name
   KEY { key-name | DEFAULT }
   VALUE key-value
```

**SECTION section-name**

A CHARACTER expression that specifies the name of the section that contains the key of interest.

In initialization files, section names appear in square brackets([]). When you specify a section name in the GET-KEY-VALUE statement, omit the square brackets.

**KEY key-name**

A CHARACTER expression that specifies the name of the key of interest.

If you specify the Unknown value (?) or the empty string (""), GET-KEY-VALUE returns a comma-separated list of all keys in the section you specified.

**DEFAULT**

Tells GET-KEY-VALUE to use the default key of section section-name.

Some applications store data in the registry under the default key of a section. This option lets you retrieve this data. For an example, see the EXAMPLES section of this entry.

This option applies only to the registry and not to initialization files.

**VALUE key-value**

The name of a CHARACTER variable to hold the value of the key of interest.

**Examples**

If the current environment resides in the registry, the GET-KEY-VALUE statement:

1. Searches the current environment for the subkey MYSECTION
2. Searches MYSECTION for the value name MYKEY
3. Assigns the value of MYKEY to the variable MYVARIABLE

If the current environment resides in an initialization file, the GET-KEY-VALUE statement:

1. Searches the section MYSECTION for the key MYKEY
2. Assigns the value of MYKEY to the variable MYVARIABLE as shown in the following example:

```plaintext
GET-KEY-VALUE SECTION "MYSECTION" KEY "MYKEY" VALUE MYVARIABLE
```

If the current environment is the registry, the GET-KEY-VALUE statement:

1. Searches the current environment for the key MYKEY
2. Assigns the value of MYKEY to the variable MYVARIABLE

If the current environment resides in an initialization file, the following example returns a comma-separated list of all section names in the initialization file:

```plaintext
GET-KEY-VALUE SECTION "" KEY "MYKEY" VALUE MYVARIABLE
```

If the current environment resides in the registry, the GET-KEY-VALUE statement:

1. Searches the current environment for the subkey MYSECTION
2. Returns a comma-separated list of all value names in MYSECTION

If the current environment resides in an initialization file, the GET-KEY-VALUE statement:

1. Searches the current environment for the section MYSECTION
2. Returns a comma-separated list of all key names in MYSECTION; for example:

```plaintext
GET-KEY-VALUE SECTION "MYSECTION" KEY "" VALUE MYVARIABLE

GET-KEY-VALUE SECTION "MYSECTION" KEY "?" VALUE MYVARIABLE
```

If the current environment resides in the registry, the following examples return a comma-separated list of subkeys under the current environment location and all value names directly under the current environment location. The delimiter @value@ separates the subkey names from the value names.

If the current environment resides in an initialization file, the following examples return a comma-separated list of all section names in the initialization file:

```plaintext
GET-KEY-VALUE SECTION "" KEY "" VALUE MYVARIABLE

GET-KEY-VALUE SECTION "" KEY "?" VALUE MYVARIABLE

GET-KEY-VALUE SECTION "?" KEY "" VALUE MYVARIABLE
```
If the current environment resides in the registry, the GET-KEY-VALUE statement:

1. Searches the current environment for the subkey MYAPP
2. Assigns the value of the default key under MYAPP to the variable MYVARIABLE

If the current environment resides in an initialization file, the following example returns an error:

```
GET-KEY-VALUE SECTION "MYAPP" KEY DEFAULT VALUE MYVARIABLE
```

### Notes

- Environments typically consist of sections, each of which can contain keys, each of which consists of a name and a value. A typical section name is COLORS. A typical key within this section consists of the name “COLOR16” and the value 255,255,0. This key attaches this particular name to this particular color. (The value represents a color specification using the red-green-blue color-naming scheme.)

The current environment might be the registry or an initialization file. The registry consists of sections called keys and subkeys arranged in a hierarchy. Keys and subkeys contain value entries, each of which consists of a value name and value data. Initialization files, by contrast, consist of a single level of sections. Sections contain entries, each of which consists of a name, an equals sign (=), and a value.

For more information on environments, see the chapter on colors and fonts in *OpenEdge Development: Programming Interfaces*.

- The current environment is either the default environment, the startup environment (an environment that a startup parameter specified), or an application environment that the LOAD statement loaded and that the USE statement made current.

- If you unload the current environment (using the UNLOAD statement) and then use the GET-KEY-VALUE statement, you access the startup environment.

### See also

LOAD statement, PUT-KEY-VALUE statement, UNLOAD statement, USE statement

---

**GET-LONG function**

Returns the signed 32-bit value at the specified memory location as an INTEGER value.

#### Syntax

```
GET-LONG ( source , position )
```

- **source**
  
  A function or variable that returns a RAW or MEMPTR value. If *source* is the Unknown value (?), GET-LONG returns the Unknown value (?).
**GET-POINTER-VALUE function**

Returns, as an INT64 value, the address of (or pointer to) the memory region associated with the specified MEMPTR variable. The returned value is based on whether the platform supports 64-bit pointers or 32-bit pointers. On a 32-bit platform, the value never gets bigger than 2GB.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

\[
\text{GET-POINTER-VALUE ( memptr-var )}
\]

**memptr-var**

A reference to a variable defined as MEMPTR. If the variable is uninitialized (has no associated memory region), the function returns 0.

**Example**

This function is particularly useful when building a structure in an MEMPTR region that references other MEMPTR regions. It allows you to obtain the pointer to one MEMPTR region and store it in the structure you create in another MEMPTR region. The following example allocates three memory regions-for a BITMAPINFO structure, a BITMAPINFOHEADER structure, and an RGB color array. It then uses the GET-POINTER-VALUE function together with the PUT-LONG statement to store pointers to the BITMAPINFOHEADER structure and an RGB color array in the BITMAPINFO structure. These structures describe a device-independent bitmap for Windows dynamic link library (DLL) routines. For more information on these bitmap structures, see your Windows Software Development Kit documentation.

**Note:** The following example only works on a 32-bit machine because it leaves space for 4 bytes for the pointer values. On a 64-bit machine, you would have to allocate 8 bytes of space.
GET-SHORT function

Returns the signed 16-bit value at the specified memory location as an INTEGER value.

Syntax

```
GET-SHORT ( source, position )
```

**source**

A function or variable that returns a RAW or MEMPTR value. If `source` is the Unknown value (?), GET-SHORT returns the Unknown value (?).

**position**

An integer value greater than 0 that indicates the byte position where you want to find the information. If `position` is greater than the length of `source`, the AVM returns the Unknown value (?). If `position` is less than 1, the AVM generates a run-time error.
Examples
For examples of how to use the GET-SHORT function, see the GET-BYTE function reference entry.

Notes
• This function supports byte-swapping only if source is a MEMPTR data type. The function will first examine the byte-order setting of the MEMPTR and then swap the bytes appropriately before interpreting them. The AVM does not swap the bytes in the MEMPTR’s memory, but does the byte-swap as it creates the return value.

• For more information on using the MEMPTR and RAW data types, see OpenEdge Development: Programming Interfaces.

See also
LENGTH function, PUT-SHORT statement, RAW function, RAW statement, SET-SIZE statement

GET-SIZE function

Returns, as an INT64 value, the allocated byte size of the memory region associated with the specified MEMPTR variable.

Note: Does not apply to SpeedScript programming.

Syntax

```
GET-SIZE ( memptr-var )
```

memptr-var
A MEMPTR variable. If the variable is uninitialized (has no associated memory region), the function returns 0.

Example
The following example allocates three memory regions-for a BITMAPINFO structure, a BITMAPINFOHEADER structure, and an RGB color array. It then displays the allocation size for each region. These structures describe a device-independent bitmap for Windows dynamic link library (DLL) routines. For more information on these bitmap structures, see your Windows Software Development Kit documentation.
GET-STRING function

Returns the null-terminated character string at the specified memory location as a CHARACTER value (not including the null terminator) or the number of bytes specified starting from the specified memory location as a CHARACTER value.

Syntax

```plaintext
GET-STRING ( source , position [, , nbytes ] )
```

source

A function or variable that returns a RAW or MEMPTR value. If `source` is the Unknown value (?), GET-STRING returns the Unknown value (?).
GET-UNSIGNED-LONG function

position

An integer value greater than 0 that indicates the byte position where you want to find the information. If position is greater than the length of source, the AVM returns the Unknown value (?). If position is less than 1, the AVM generates a run-time error.

numbytes

An integer value greater than 0 that indicates how many bytes to convert into the CHARACTER value that is returned. If numbytes is not specified, or is -1, GET-STRING( ) returns all bytes until it encounters a NULL value.

Examples

For examples of how to use the GET-STRING function, see the GET-BYTE function reference entry.

Note

For more information on using the MEMPTR and RAW data types, see OpenEdge Development: Programming Interfaces.

See also

LENGTH function, PUT-STRING statement, RAW function, RAW statement, SET-SIZE statement

GET-UNSIGNED-LONG function

Returns the unsigned 32-bit value at the specified memory location as an INT64. This is analogous to the GET-UNSIGNED-SHORT function, except with a 32-bit value.

Syntax

```
GET-UNSIGNED-LONG ( source , position )
```

source

A function or variable that returns a RAW or MEMPTR value. If source is the Unknown value (?), GET-UNSIGNED-LONG returns the Unknown value (?).

position

An INTEGER or INT64 value greater than 0 that indicates the byte position where you want to find the information. If position is greater than the length of source, the AVM returns the Unknown value (?). If position is less than 1, the AVM generates a run-time error.

Notes

- When returning the value from GET-UNSIGNED-LONG( ) to an INTEGER, if the value exceeds the maximum value of an INTEGER, the AVM generates a run-time error.

- This function supports byte-swapping only if source is a MEMPTR data type. The function will first examine the byte-order setting of the MEMPTR and then swap the bytes appropriately before interpreting them. The AVM does not swap the bytes in the MEMPTR’s memory, but does the byte-swap as it creates the return value.

- For more information on using the MEMPTR and RAW data types, see OpenEdge Development: Programming Interfaces.

See also

LENGTH function, PUT-UNSIGNED-LONG statement, RAW function, RAW statement, SET-SIZE statement
GET-UNSIGNED-SHORT function

Returns the unsigned 16-bit value at the specified memory location as an INTEGER value.

Syntax

```
GET-UNSIGNED-SHORT ( source, position )
```

**source**

A function or variable that returns a RAW or MEMPTR value. If `source` is the Unknown value (?), GET-UNSIGNED-SHORT returns the Unknown value (?).

**position**

An integer value greater than 0 that indicates the byte position where you want to find the information. If `position` is greater than the length of `source`, the AVM returns the Unknown value (?). If `position` is less than 1, the AVM generates a run-time error.

**Examples**

For examples of how to use the GET-UNSIGNED-SHORT function, see the GET-BYTE function reference entry.

**Notes**

- This function supports byte-swapping only if `source` is a MEMPTR data type. The function will first examine the byte-order setting of the MEMPTR and then swap the bytes appropriately before interpreting them. The AVM does not swap the bytes in the MEMPTR’s memory, but does the byte-swap as it creates the return value.

- For more information on using the MEMPTR and RAW data types, see *OpenEdge Development: Programming Interfaces*.

**See also**

LENGTH function, PUT-SHORT statement, RAW function, RAW statement, SET-SIZE statement

GO-PENDING function

Returns a TRUE value if, within an EDITING phrase, an APPLY statement results in a GO action. The GO action is deferred until the end of the EDITING phrase.

This function is supported only for backward compatibility.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
GO-PENDING
```

**Example**

The `r-gopend.p` procedure lets you update some of the fields in each customer record. If you press GO when the value in the current balance field is greater than the balance in the credit-limit field, the UPDATE statement does not end. Instead, it continues prompting you for input until you correct the problem and then press GO.
GT or > operator

Returns a TRUE value if the first of two expressions is greater than the second expression.

Syntax

\[ \text{expression} \{ \text{GT} | > \} \text{expression} \]

expression

A constant, field name, variable name, or any combination of these. The expressions on either side of the GT or > must be of the same data type, although one might be integer and the other decimal.

Example

This procedure lists all items that have a negative OnHand quantity or more than 90% of the OnHand inventory currently allocated:

```
FOR EACH Item NO-LOCK:
  IF Item.Allocated > 0 THEN IF (Item.OnHand <= 0) OR
    (Item.Allocated / Item.OnHand > .9) THEN
END.
```

Notes

- By default, the AVM uses the collation rules you specify to compare characters and sort records. The collation rules specified with the Collation Table (-cpcoll) startup parameter take precedence over a collation specified for any database the AVM accesses during the session, except when the AVM uses or modifies pre-existing indexes. If you do not specify a collation with the -cpcoll startup parameter, the AVM uses the language collation rules defined for the first database on the command line. If you do not specify a database on the command line, the AVM uses the collation rules with the default name "basic" (which might or might not exist in the convmap.cp file).
• If either of the expressions is the Unknown value (?), then the result is the Unknown value (?); if both of the expressions are the Unknown value (?), then the result is FALSE.

• You can compare character strings with GT. Most character comparisons are case insensitive in ABL. That is, upper-case and lower-case characters have the same sort value. However, it is possible to define fields and variables as case sensitive (although it is not advised, unless strict ANSI SQL adherence is required). If either *expression* is a field or variable defined as case sensitive, the comparison is case sensitive and “Smith” does not equal “smith”.

• Characters are converted to their sort code values for comparison. Using the default case-sensitive collation table, all uppercase letters sort before all lowercase letters (for example, a is greater than Z, but less than b). Note also that in character code uppercase A is less than [ , \, ^ , _, and ’, but lowercase a is greater than these.

• You cannot compare data of different DATE, DATETIME, and DATETIME-TZ data types to each other using GT. You must first convert different date and datetime data types to the same data type before doing a comparison between them.

• You can use GT to compare a LONGCHAR variable to another LONGCHAR or CHARACTER variable. The variable values are converted to -cpinternal for comparison and must convert without error, or the AVM raises a run-time error.

• You cannot use GT to compare one CLOB field to another.

GUID function

Converts a universally unique identifier (UUID) value into a globally unique identifier (GUID) value. This function returns a GUID as a 36-character string value consisting of 32 hexadecimal digits (0 through 9 and A through F) and 4 hyphens formatted as follows (where X is a hexadecimal digit): 00000000-0000-0000-0000-000000000000.

**Syntax**

```plaintext
GUID( [ UUID ] )
```

**UUID**

An optional 16-byte raw UUID value to be converted. If the specified UUID is not exactly 16 bytes in length, the AVM returns the Unknown value (?). If not specified, the AVM generates a UUID and then converts it into a GUID.

**Example**

The following code fragment illustrates how to use the GUID function:

```plaintext
DEFINE VARIABLE MyUUID AS RAW NO-UNDO.
DEFINE VARIABLE vGUID AS CHARACTER NO-UNDO.
ASSIGN
  MyUUID = GENERATE-UUID
  vGUID = GUID(MyUUID).
```

**See also** GENERATE-UUID function
HANDLE function

Converts a string representation of a handle to a valid handle.

Syntax

HANDLE ( handle-string )

Caution: Use this function only to convert a handle previously stored as a string value back to a valid handle. If you convert an arbitrary string to handle using this function and then reference the new handle, a system error will occur. If you use the VALID-HANDLE function to validate a handle generated from an arbitrary string value, a system error will occur.

handle-string

A string representation of a handle. Since handles are integer values, the string must contain only numeric characters.

Example

The following procedure creates a frame, stores the handle of the frame as a string value, deletes the frame, converts the string representation of the frame handle back to a valid handle, and then tests if the handle is valid:

r-widhd.p

DEFINE VARIABLE whand AS HANDLE NO-UNDO.
DEFINE VARIABLE chand AS CHARACTER NO-UNDO.

CREATE FRAME whand.
chand = STRING(whand).
DELETE WIDGET whand.
whand = HANDLE(chand).
MESSAGE VALID-HANDLE(whand) VIEW-AS ALERT-BOX INFORMATION BUTTONS OK.

The VALID-HANDLE function returns a FALSE value because the frame was deleted and the handle is no longer valid.

Notes

• The HANDLE function can convert the string representation of procedure, system, and widget handles.

• For SpeedScript, the only valid use is to convert the handle of a QUERY object that you create using the CREATE WIDGET statement.

See also

CREATE widget statement, DATE function, DECIMAL function, INTEGER function, STRING function, VALID-HANDLE function

HEX-DECODE function

Converts a character string consisting of an even number of hexadecimal digits (0 through 9 and A through F) into a RAW value.
HEX-ENCODE function

Syntax

HEX-ENCODE( expression )

expression

A character expression containing the value you want to convert. If the expression does not contain an even number of hexadecimal digits, or it is the Unknown value (?), the result is the Unknown value (?). If the expression is a zero-length value, the result is a zero-length value.

Example

The following code fragment illustrates how to use the HEX-DECODE function:

```
DEFINE VARIABLE vRaw as RAW NO-UNDO.
vRaw = HEX-DECODE(HEX-ENCODE(GENERATE-UUID)).
```

See also

HEX-ENCODE function

HEX-ENCODE function

Converts a RAW value into a character string consisting of an even number of hexadecimal digits (0 through 9 and A through F).

Syntax

HEX-ENCODE( expression )

expression

A RAW expression containing the value you want to convert. If the expression is the Unknown value (?), the result is the Unknown value (?). If the expression is a zero-length value, the result is a zero-length value.

Example

The following code fragment illustrates how to use the HEX-ENCODE function:

```
DEFINE VARIABLE MyUUID AS RAW NO-UNDO.
DEFINE VARIABLE vChar AS CHARACTER NO-UNDO.
ASSIGN
MyUUID = GENERATE-UUID
vChar = HEX-ENCODE(MyUUID).
```

See also

HEX-DECODE function

HIDE statement

Makes a widget invisible (sets its VISIBLE attribute to FALSE), or clears the message area for a window, or hides all widgets and clears messages in a window.
### HIDE statement

**Note:** Does not apply to SpeedScript programming.

#### Syntax

```
HIDE [ STREAM stream | STREAM-HANDLE handle ]
[ widget-phrase | MESSAGE | ALL ]
[ NO-PAUSE ]
[ IN WINDOW window ]
```

**STREAM stream**

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream.

**STREAM-HANDLE handle**

Specifies the handle to a stream. If `handle` is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in *OpenEdge Development: Programming Interfaces* for more information on streams and stream handles.

**widget-phrase**

The widget you want to hide. You can hide windows, frames, and field-level widgets. You cannot hide menus. If you do not use this option or the MESSAGE or ALL options, HIDE hides the default frame for the block that contains the HIDE statement.

**MESSAGE**

Hides all messages displayed in the message area for the specified window. If you use the PUT SCREEN statement to display data in the message area, the HIDE MESSAGE statement does not necessarily hide that data.

**ALL**

Hides all widgets in the window and clears the message area for the window.

**NO-PAUSE**

Does not pause before hiding. Ordinarily, if data has been displayed, but there have been no data entry operations or pauses, the AVM prompts you to press `SPACEBAR` to continue before hiding the widget.

**IN WINDOW window**

Specifies which window the HIDE statement acts on. The value `window` must evaluate to the handle of a window. If you do not use the IN WINDOW option, the current window is assumed.

#### Example

The following example uses the HIDE statement to hide selected frames. The DISPLAY statements re-display the frames when the loop iterates.
**Notes**

- When a block iterates, any display frame that is scoped to the block or to a nested block is tagged for hiding (unless you have used the NO-HIDE option in the Frame phrase), but is not hidden. Then, the first frame activity of the next iteration (a DISPLAY, INSERT, PROMPT-FOR, SET, VIEW, or UPDATE statement) for a frame scoped to the block or to a nested block causes all tagged frames to be hidden.

  The frame associated with that first frame activity is not hidden because it would be redisplayed immediately. This improves display time. When a block ends, the AVM removes the hide tags from all the frames scoped to that block or to nested blocks.

- Frames displayed by procedures within a block or within a nested block are treated the same as other frames in a nested block.

- When the AVM displays a frame and there is not enough room in the window, it automatically hides one or more frames. Frames are hidden one at a time, starting with the lowest frame in the window, until there is room to fit the new frame.

- It is more efficient to HIDE ALL than to HIDE each frame individually.

- If you hide a PAGE-TOP or PAGE-BOTTOM frame, it is removed from the list of active frames for printing at the top or bottom of each page.

- If you are working in a PAGE-TOP or PAGE-BOTTOM frame, use the VIEW or DISPLAY statement to activate that frame. The VIEW statement does not display a PAGE-TOP or PAGE-BOTTOM frame. It activates the frame so that when a new page begins or ends, the AVM displays the frame. If you use the HIDE statement to hide a PAGE-TOP or PAGE-BOTTOM frame, the AVM deactivates that frame so that it can no longer be displayed unless it is reactivated with a VIEW or DISPLAY statement.
• If output is not directed to the terminal, HIDE has no effect on the terminal display.

• In batch mode, the HIDE statement produces an error. If you want to remove the contents of a frame, use the CLEAR statement instead.

• You can use HIDE MESSAGE to hide a message.

• If you invoke the HIDE statement for a field-level widget or child frame, the HIDDEN attribute of the specified field-level widget or child frame is also set to TRUE. However, if you invoke the HIDE statement for a child window, the HIDDEN attribute of the child window is unaffected.

• When you HIDE a visible window, any visible descendant windows are hidden also (including iconified descendants), but any visible ancestor windows remain unaffected. However, if you HIDE a window whose HIDDEN attribute is currently set to TRUE, its descendant windows remain unaffected.

See also

CLEAR statement, VIEW statement, Widget phrase, Stream object handle
**IF...THEN...ELSE function**

Evaluates and returns one of two expressions, depending on the value of a specified condition.

**Syntax**

```
IF condition THEN expression1 ELSE expression2
```

**condition**

An expression whose value is logical (TRUE or FALSE).

**expression1**

A constant, field name, variable name, or expression. If the `condition` is TRUE, then the function returns this value.

**expression2**

A constant, field name, variable name, or expression whose value is of a data type that is compatible with the data type of `expression1`. If the `condition` is FALSE or the Unknown value (?), then the function returns this value.

**Example**

You can use the IF...THEN...ELSE function when you want to sort records in an unusual order. In this example, the Customers are sorted so that those with a Balance greater than $10,000 appear first, then those with Balances between $1,000 and $10,000, and finally those with Balance of $1,000 or less:

```
r-ifelsf.p
```

```
FOR EACH Customer NO-LOCK BY IF Customer.Balance > 10000 THEN 1 ELSE (IF Customer.Balance > 1000 THEN 2 ELSE 3) BY Customer.SalesRep:
END.
```

**IF...THEN...ELSE statement**

Makes the execution of a statement or block of statements conditional. If the value of the expression following the IF statement is TRUE, the AVM processes the statements following the THEN statement. Otherwise, the AVM processes the statements following the ELSE statement.

**Syntax**

```
IF expression THEN { block | statement }
[ ELSE { block | statement } ]
```

**expression**

A constant, field name, variable name, or expression whose value is logical (TRUE or FALSE). The expression can include comparisons, logical operators, and parentheses.
THEN

Describes the block statement to process if the expression is TRUE.

block

The block statement that contains the code you want to process if expression is TRUE. See the DO statement, FOR statement, and REPEAT statement reference entries for more information. If you do not start a block, you can process just one statement after the IF keyword or the ELSE keyword.

Any block or blocks you use in an IF . . . THEN . . . ELSE statement can contain other blocks or other IF . . . THEN . . . ELSE statements.

statement

A single ABL statement. The statement can be another IF . . . THEN . . . ELSE statement. If you want to use more than one statement, enclose those statements in a DO, FOR EACH, or REPEAT block.

ELSE

Describes the block statement to process if the expression is FALSE or the Unknown value (?). The ELSE option is not required.

Example

The r-ifelse.p procedure creates a report in a file that lists Customers whose Orders have been shipped, but who have not paid for those Orders:
First, the procedure writes report headers to the `ovrdue.lst` file. Next, the outer FOR EACH block reads each of the Orders using a DISPLAY statement to display information on each Order. If there are no values in the ShipDate and PromiseDate fields, the procedure prompts you to enter a promise date. The procedure then prompts if the order has been shipped. If it has, supply a ship date.

If there is a ship date and a promise date for an order, the procedure prompts if the order has been paid for. If not, the procedure displays the order information to the file.
FILE name
   [ { IMAGE-SIZE | IMAGE-SIZE-CHARS | IMAGE-SIZE-PIXELS } ]
   width BY height
   [ FROM { X n Y n | ROW n COLUMN n } ]

{ IMAGE-SIZE | IMAGE-SIZE-CHARS | IMAGE-SIZE-PIXELS }}
   width BY height
   [ FROM { X n Y n | ROW n COLUMN n } ]

FILE name

A character expression that specifies the name of an operating system file that contains an image. If you do not specify a full pathname, ABL searches your PROPATH for the file. If you do not supply a suffix, ABL searches for files with the extension .bmp, .ico, or .cur in Windows. The image contained within the file must be in a format that is appropriate for the target platform. The file is not read until the image is displayed.

[ IMAGE-SIZE | IMAGE-SIZE-CHARS ]

Specifies that the unit of measure when reading the image is characters.

IMAGE-SIZE-PIXELS

Specifies that the unit of measure when reading the image is pixels.

width

Specifies the width of the image. The value width must be an integer constant. If the image is larger than the size you specify, the AVM crops the image to the specified size.

height

Specifies the height of the image. The value height must be an integer constant. If the image is larger than the size you specify, the AVM crops the image to the specified size.

FROM { X n Y n | ROW n COLUMN n }

Two integer constants (n) that specify the offset inside the image file where the AVM starts reading the image. If you specify X and Y, the offset is measured in pixels; if you specify ROW and COL, the offset is measured in characters.

Example

See the DEFINE IMAGE statement reference entry for an example.

Notes

- Use one of the image size options in conjunction with the FILE option to make a compile-time association between the image file and the image widget; the image file does not have to exist at this point.

- Use one of the image size options without the FILE option to create an image widget that is not associated with an image file at compile time. You can then make the association at run time.
• Use the FILE option without one of the image size options if you do not know the size of the image and want ABL to determine the size at compile time. If you do this, ABL uses the entire image. Also note that the image file must exist or a compiler error will occur.

• In Windows, you can specify a URL pathname. If you do not specify a fully-qualified URL, ABL searches in the PROPATH for the file. Valid URL protocols include HTTP and HTTPS.

**Note:** URL pathnames cannot contain the percent symbol (%). If an error exists in a URL specified on the PROPATH, ABL continues searching with the next PROPATH entry.

• Table 42 lists the image file formats that are currently supported for use on button and image widgets.

IMPORT statement

Reads a line from an input file that might have been created by EXPORT.

Syntax

```
IMPORT [ STREAM stream | STREAM-HANDLE handle ]  
{  
  [ DELIMITER character ]  
  {  
    field | ^  
  }  
  ...  
  |  
  [ DELIMITER character ]  
  record  
  [ EXCEPT field ... ]  
  
  UNFORMATTED field  
}  
[ NO-LOBS ]  
[ NO-ERROR ]
```

```
IMPORT [ STREAM stream | STREAM-HANDLE handle ]  
{  
  memptr | longchar  
}
```

STREAM stream

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream.

See also

DEFINE BUTTON statement, DEFINE IMAGE statement, FORM statement
STREAM-HANDLE handle

Specifies the handle to a stream. If handle it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams and stream handles.

DELIMITER character

The character used as a delimiter between field values in the file. The character parameter must be a quoted single character. The default is a space character.

If you specify more than one character as a delimiter, ABL uses the first character as the delimiter.

field

The name of a field or variable to which you are importing data. The field or variable must have either the CHARACTER or RAW data type. If the data type is RAW, the IMPORT statement reads enough characters to fill the current length of the variable. If not enough characters are available to fill the current length, the length is reset to the number of characters read.

^ Use a caret (^) to skip a data value in each input line when input is being read from a file.

record

The name of a record buffer. All of the fields in the record are processed exactly as if you had named each of them individually. The record you name must contain at least one field. To use IMPORT with a record in a table defined for multiple databases, qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

EXCEPT field

Tells the AVM to import all the fields except those listed in the EXCEPT phrase.

UNFORMATTED field

Treats each line of the input file as a single string value. In this case, the field parameter must be a single CHARACTER or RAW field or variable. You can use this option to read text files one line at a time.

Use this option on a RAW variable to import binary data that was not exported to the file as RAW data.

NO-LOBS

Directs the AVM to ignore large object data when importing records that contain BLOB or CLOB fields.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent
side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

memptr

A variable of data type MEMPTR that contains the imported text. The IMPORT statement may contain a MEMPTR in its field list as long as it is the only field in the list.
IMPORT statement

**longchar**

A variable of data type LONGCHAR that contains the imported text. The IMPORT statement may contain a LONGCHAR in its field list as long as the LONGCHAR is the only field in the list and is the result of an EXPORT statement.

**Examples**

This procedure takes the data in file `customer.d` and enters it into the OpenEdge database table `Customer`. The procedure uses the DISABLE TRIGGERS statement to stop the AVM from executing any triggers for the CREATE, WRITE, and ASSIGN events when loading the data.

**Note:** The imported files, `customer.d` and `custdump2`, in the next two examples are created by running the example programs under EXPORT.

**r-imprt.p**

```plaintext
INPUT FROM customer.d.
DISABLE TRIGGERS FOR LOAD OF Customer.
REPEAT:
  CREATE Customer.
  IMPORT Customer.
END.
INPUT CLOSE.
```

If the file uses a delimiter other than a space to separate fields, use the DELIMITER option of the IMPORT statement.

**r-cstin.p**

```plaintext
DEFINE VARIABLE cnum NO-UNDO LIKE Customer.CustNum.
DEFINE VARIABLE cname NO-UNDO LIKE Customer.Name.
DEFINE VARIABLE cmax NO-UNDO LIKE Customer.CreditLimit.

INPUT FROM custdump2.
FOR EACH Customer:
  IMPORT DELIMITER ";" cnum cname cmax.
  DISPLAY cnum cname cmax.
END.
INPUT CLOSE.
```

You can use the UNFORMATTED option to read the contents of a standard text file. For example, the following procedure reads and displays the contents of the `hello` file:

**r-hello.p**

```plaintext
DEFINE VARIABLE text-string AS CHARACTER NO-UNDO FORMAT "x(76)".

INPUT FROM VALUE(SEARCH("hello"))．
DO WHILE TRUE ON ENDKEY UNDO, LEAVE:
  IMPORT UNFORMATTED text-string.
  DISPLAY text-string WITH DOWN FRAME x.
  DOWN WITH FRAME x NO-LABELS.
END.
INPUT CLOSE.
```
In the MEMPTR version of the IMPORT statement, the MEMPTR must be pre-allocated to the size needed for reading. To get the length to read for an imported file, use the FILE_INFO system handle and the SET-SIZE statement as follows:

```
DEFINE VARIABLE bb AS MEMPTR NO-UNDO.
ASSIGN
  FILE-INFO:FILE-NAME = "big.in"
  SET-SIZE(bb) = FILE-INFO:FILE-SIZE.
INPUT FROM "big.in" BINARY NO-CONVERT.
IMPORT bb.
INPUT CLOSE.
```

**Notes**

- The IMPORT statement must follow a statement that redirects the input source (usually an INPUT FROM statement). You cannot use the IMPORT statement to read data from the screen.

- If you do not use the UNFORMATTED option, the data in the input stream must be in a **standard format** to be read back into ABL. You must enclose all character fields in quotes (""’) if they contain any delimiter characters. If you want to import any quotes contained in the data, replace them with two quotes ("’’”). You must display the Unknown value (?) as an unquoted question mark.

- If an input data line contains an unquoted hyphen in place of a data value, then the corresponding field is skipped, as it is in UPDATE. If you specify a hyphen (-) as the delimiter character, all hyphens are treated as delimiters. If you use the UNFORMATTED option, the hyphen is treated the same as any other character.

- A period (.) on a line by itself is treated as an end-of-file indicator. The ENDKEY is applied, but the file or stream remains open for input.

- Data read in with IMPORT is not restricted by frame-related format statements, as is data read in by SET or UPDATE. Since IMPORT does not have to validate the input stream, it is faster than SET or UPDATE.

- When importing records that contain a BLOB or CLOB field, the AVM uses the value stored in the BLOB or CLOB field of the exported record to determine whether or not the exported record has an associated object data file to import. If the BLOB or CLOB field in the exported record contains the Unknown value (?), the AVM stores the Unknown value (?) in the BLOB or CLOB field of the new or updated record. If the BLOB or CLOB field in the exported record contains a filename, the AVM imports the associated object data. If an updated record already has object data associated with it, the AVM deletes that object data before importing the new object data.

  The AVM raises the ERROR condition if an object data file cannot be found or read.

- Use the NO-LOB5 option with the IMPORT statement to ignore large object data when importing records that contain BLOB or CLOB fields. More specifically:

  - When you import an exported record into a new record, and the BLOB or CLOB field of the exported record contains either the Unknown value (?) or a filename, the AVM sets the value of the BLOB or CLOB field in the newly imported record to the Unknown value (?); the AVM does not create any object data.
– When you import an exported record as an update to an existing record, and the BLOB or CLOB field of the exported record contains either the Unknown value (?) or a filename, the AVM does not change the value of the BLOB or CLOB field in the existing record and neither creates nor overwrites object data.

- The IMPORT statement reads large object data files from the directory specified as the input data source in the INPUT FROM statement, by default. You can use the LOB-DIR option on the INPUT FROM statement to specify the directory from which the IMPORT statement reads BLOB and CLOB data files.

- IMPORT is sensitive to the Date Format (-d), Century (-yy), and European Numeric Format (-E) parameters. When loading data with the IMPORT statement, use the same settings that you used with the EXPORT statement.

- When importing DATETIME and DATETIME-TZ data, the data format must be fixed and must conform to the ISO 8601 standard for date/time representations (YYYY-MM-DDTHH:MM:SS.SSS+HH:MM). For DATETIME, there is no time zone offset.

- ABL interprets the null character as a terminator.

- The UNFORMATTED option forces IMPORT to read one physical line at a time. A physical line ends with a newline or linefeed character.

- In the MEMPTR version of the IMPORT statement, the MEMPTR must be pre-allocated to the size needed for reading. See the example, r-impmem.p, above.

- When importing a CLOB or LONGCHAR variable, the AVM uses the code page information in the exported file header to determine the variable’s code page. However, the COPY-LOB statement is recommended for Unicode CLOB or LONGCHAR variables.

DEFINE STREAM statement, DISABLE TRIGGERS statement, DISPLAY statement, EXPORT statement, INPUT FROM statement, INPUT CLOSE statement, PUT statement, Stream object handle, STRING function

INDEX function

Returns an INTEGER value that indicates the position of the target string within the source string.

Syntax

INDEX ( source , target [ , starting ] )

source

A CHARACTER or LONGCHAR expression.

target

A CHARACTER or LONGCHAR expression whose position you want to locate in source. If target does not exist within source, INDEX returns a 0.
An integer that specifies at which left-most position in the string to start the search. For example, INDEX("abcdefabcdef","abc",6) returns 7.

Examples

For this example, you must enter 1, 2, 3, 4, or 5. The INDEX function checks if the digit exists in the string "12345".

r-index.p

| DEFINE VARIABLE x AS CHARACTER NO-UNDO FORMAT "9"  |
| LABEL "Enter a digit between 1 and 5".               |
| DEFINE VARIABLE show AS CHARACTER NO-UNDO FORMAT "x(5)" EXTENT 5 |
| LABEL "Literal" INITIAL ["One", "Two", "Three", "Four", "Five"]. |

REPEAT:
  SET x AUTO-RETURN.
  IF INDEX("12345",x) = 0 THEN DO:
    MESSAGE "Digit must be 1,2,3,4, or 5. Try again.".
    UNDO, RETRY.
  END.
  ELSE DISPLAY show[INTEGER(x)].
END.

This procedure also uses the starting option:

r-index2.p

| DEFINE VARIABLE positions AS CHARACTER NO-UNDO FORMAT "x(60)". |
| DEFINE VARIABLE sentence AS CHARACTER NO-UNDO FORMAT "x(72)".    |
| DEFINE VARIABLE vowel AS CHARACTER NO-UNDO FORMAT "x".          |
| DEFINE VARIABLE found AS INTEGER NO-UNDO.                      |
| DEFINE VARIABLE loop AS INTEGER NO-UNDO.                       |
| DEFINE VARIABLE start AS INTEGER NO-UNDO.                      |

FORM sentence LABEL "Type in a sentence" WITH FRAME top
  TITLE "This program will tell where the vowels are in a sentence.".

SET sentence WITH FRAME top.
DO loop = 1 TO 5:
  ASSIGN
    positions = ""
    vowel = SUBSTRING("aeiou",loop,1)
    start = 1
    found = INDEX(sentence,vowel,start).
  DO WHILE found > 0:
    ASSIGN
      positions = positions + STRING(found) + " ".
      start = found + 1
      found = INDEX(sentence,vowel,start).
  END.
  DISPLAY vowel LABEL "Vowel" positions LABEL "Is found at locations..." WITH 5 DOWN.
END.

Notes

- If either operand is case sensitive, then the search is case sensitive.
- If the target string is null, the result is 0.
The INDEX function is double-byte enabled. You can specify target and source strings for the INDEX function that contain double-byte characters.

See also: LOOKUP function, R-INDEX function

INPUT function

References the value of a field in a frame. For example, if you use the PROMPT-FOR statement to get input from the user, PROMPT-FOR stores that information in the screen buffer. You can use the INPUT function to refer to that information.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
INPUT [ FRAME frame ] field
```

**FRAME frame**

The name of the frame that contains the field named by the field argument. If you do not name a frame, the INPUT function starts with the current frame and searches outward until it finds the field you name with the field argument.

**field**

The name of a field or variable whose value is stored in the screen buffer. The specified field must be viewed as a fill-in or text widget.

**Example**

This procedure displays the current CreditLimit for a Customer. The PROMPT-FOR statement prompts the user for a new CreditLimit value and stores the supplied data in the screen buffer. The procedure uses the INPUT function to point to the data in that buffer.

```
FOR EACH Customer:
  DISPLAY Customer.CustNum Customer.Name Customer.CreditLimit
  LABEL "Current credit limit"
  WITH FRAME a 1 DOWN ROW 1.
  PROMPT-FOR Customer.CreditLimit LABEL "New credit limit"
  WITH SIDE-LABELS NO-BOX ROW 10 FRAME b.
  IF INPUT FRAME b Customer.CreditLimit <> Customer.CreditLimit THEN DO:
    DISPLAY "Changing max credit of" Customer.Name SKIP
    "From" Customer.CreditLimit "to" INPUT FRAME b Customer.CreditLimit
    WITH FRAME c ROW 15 NO-LABELS.
    Customer.CreditLimit = INPUT FRAME b Customer.CreditLimit.
  END.
  ELSE DISPLAY "No change in credit limit" WITH FRAME d ROW 15.
  END.
```

If the user enters a new value, the procedure displays a message that the value has been changed. If the user enters the same value, the procedure displays a message that the credit-limit has not been changed.
Notes

• If you use a field or variable that is referenced with INPUT in more than one frame, then ABL uses the value in the frame most recently introduced in the procedure. To ensure that you are using the appropriate frame, use the FRAME option with the INPUT function to reference a particular frame.

• If you use the INPUT function for a character field whose format contains fill characters, then the value of the function does not contain the fill characters. The fill characters are not stored in the database field or variable, but are instead supplied during display formatting of the data.

INPUT CLEAR statement

Clears any keystrokes buffered from the keyboard, discarding any type-ahead characters. The INPUT CLEAR statement is useful when you want to make sure the AVM clears out extra characters in the input statement that could follow a field entry that is too long.

Note: Does not apply to SpeedScript programming.

Syntax

```plaintext
INPUT CLEAR
```

Example

This menu procedure tests each key the user presses. If the user presses a key other than 1, 2, or 3, the AVM clears the keyboard buffer and displays a message.

```plaintext
DISPLAY "     Please choose     " SKIP
" 1  Run order entry  " SKIP
" 2  Run receivables  " SKIP
" 3  Exit           " WITH CENTERED FRAME menu.
REPEAT:
  READKEY.
  IF LASTKEY = KEYCODE("1") THEN RUN ordentry.
  ELSE
    IF LASTKEY = KEYCODE("2") THEN RUN receive.
    ELSE
      IF LASTKEY = KEYCODE("3") THEN QUIT.
      ELSE DO:
        MESSAGE "Sorry, that is not a valid choice".
        INPUT CLEAR.
      END.
    END.
  END.
END.
```

Notes

• In Windows, the keyboard type-ahead buffer can contain a maximum of 16 characters.

• If the current input source is not the keyboard, the INPUT CLEAR statement has no effect.

• INPUT CLEAR is not available on the Windows GUI platform after Progress Version 7.3D. It is available in Windows character and non-Windows GUI or character platforms.

See also

EDITING phrase
INPUT CLOSE statement

Closes the default input source or the stream you name.

Syntax

```
INPUT [ STREAM stream | STREAM-HANDLE handle ] CLOSE
```

STREAM stream

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream. See the `DEFINE STREAM` statement reference entry and *OpenEdge Development: Programming Interfaces* for more information on streams.

STREAM-HANDLE handle

Specifies the handle to a stream. If `handle` it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in *OpenEdge Development: Programming Interfaces* for more information on streams and stream handles.

Example

Instead of getting input from the terminal, the following procedure gets input from a file named `r-in.dat`. The SEARCH function determines the full pathname of this file.

```
INPUT FROM VALUE(SEARCH("r-in.dat")).
REPEAT:
  FIND Customer USING INPUT Customer.CustNum.
  ASSIGN Customer.CreditLimit.
END.

INPUT CLOSE.
```

Here is what the contents of the `r-in.dat` file looks like:

```
1 55800
2 41300
5 88000
```

The PROMPT-FOR statement uses the first data item (1) as the `CustNum` and the second data item (55800) as the `CreditLimit`. The FIND statement finds the Customer whose `CustNum` is 1 and assigns the value of 55800 as that Customer’s credit limit. On the next iteration of the REPEAT block, the PROMPT-FOR statement uses the value of 2 as the `CustNum` the value of 41300 as the `CreditLimit`, etc.

The INPUT CLOSE statement closes the input source, resetting it to the terminal. When you run this procedure, the data in the window is simply an echo of the data as the procedure is reading it in from the `taxno.dat` file. If you do not want to display the data, add the word NO-ECHO to the end of the INPUT FROM statement.
Notes

- The default input source is the terminal unless the procedure was called by another procedure. In that case, the default input source is the one that was active in the calling procedure when the second procedure was called.

- When a procedure ends, the AVM closes all input sources established in that procedure.

- For more information on input sources, see OpenEdge Development: Programming Interfaces.

See also

DEFINE STREAM statement, INPUT FROM statement, Stream object handle

INPUT FROM statement

Specifies the new input source for a stream.

Syntax

```
INPUT [ STREAM stream | STREAM-HANDLE handle ] FROM
{   opsys-file
    | opsys-device
    | TERMINAL
    | VALUE ( expression )
    | OS-DIR ( directory ) [ NO-ATTR-LIST ]
} [ LOB-DIR { constant | VALUE ( expression ) } ] [ BINARY ] [ ECHO | NO-ECHO ] [ MAP protermcap-entry | NO-MAP ] [ UNBUFFERED ] [ NO-CONVERT ] [ { CONVERT
    [ TARGET target-codepage ]
    [ SOURCE source-codepage ]
} ]
```

STREAM stream

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream. See the DEFINE STREAM statement reference entry and OpenEdge Development: Programming Interfaces for more information on streams.

STREAM-HANDLE handle

Specifies the handle to a stream. If handle it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams and stream handles.
**INPUT FROM statement**

*opsys-file*

The absolute or relative pathname of a file that contains the data you want to input. Any relative pathname is relative to the current working directory. Remember that UNIX file names are case sensitive.

*opsys-device*

The name of a UNIX or Windows device.

**TERMINAL**

Indicates that you want to get input from your terminal. The terminal is the default input source. You cannot use TERMINAL with STREAM.

**VALUE ( expression )**

An expression whose value is the source where you want to input data.

**OS-DIR (directory)**

Indicates that you want your input to be the filenames found in `directory`. The value of `directory` is a character expression specifying an operating system directory. If `directory` is not a directory or you do not have permission to read it, then the INPUT statement raises ERROR. Otherwise, the AVM generates the directory list and feeds it back to the calling program through the INPUT stream. An INPUT CLOSE statement discards any unread filenames from the list.

Each line read from the input stream is a string composed of three tokens: the file’s base name, the file’s absolute path name, and an attribute list indicating the file type, which consists of one or more of the characters listed below.

You will get one of the following characters:

- **F** — Regular file or FIFO pipe
- **D** — Directory
- **S** — Special device
- **X** — Unknown file type

You might also get one or more of the following characters:

- **H** — Hidden file
- **L** — Symbolic link
- **P** — Pipe file

If you specify the NO-ATTR-LIST option, you will not get the attribute list for any line read from the input stream.

The two filenames in each input line are in EXPORT format; that is, they are enclosed in quotes and any embedded quotes are doubled. This means that INPUT FROM can process any filename, containing any characters, as long as IMPORT is used to read the input.
NO-ATTR-LIST

Omits the attribute list indicating the file type. This can speed up program execution. The following example illustrates this form of the statement:

```
INPUT FROM OS-DIR("c:\mydir") NO-ATTR-LIST.
```

LOB-DIR `{ constant | VALUE ( expression ) }`

Specifies the directory from which you want the IMPORT statement to read large object data files (such as BLOB and CLOB data files). The `constant` and `expression` arguments are character expressions that evaluate to an absolute pathname or a relative pathname (relative to the directory specified for `opsys-file`).

If the specified character expression evaluates to either the Unknown value (?) or a directory that does not exist, or you do not have permission to read the specified directory, the AVM raises the ERROR condition.

The LOB-DIR option is valid only when you specify an operating system file as the input data source.

BINARY

Allows all input to be read directly without any conversion or interpretation. By default, NUL (\0) terminates character strings, and other control characters are interpreted as expected for the operating system.

ECHO

Displays all input data on the current output device. Data is echoed by default.

NO-ECHO

Accepts input data without displaying it on the current output device. If you do not use this option, INPUT FROM automatically displays input data on the current output device.

MAP protermcap-entry | NO-MAP

The `protermcap-entry` value is an entry from the PROTERMCAP file. Use MAP to read from an input stream that uses a different character translation from the current stream. Typically, `protermcap-entry` is a slash-separated combination of a standard device entry and one or more language-specific add-on entries (MAP laserwriter/french or MAP hp2/spanish/italian, for example). The AVM uses the PROTERMCAP entries to build a translation table for the stream. Use NO-MAP to make the AVM bypass character translation altogether. See OpenEdge Development: Internationalizing Applications for more information on PROTERMCAP and national language support.

UNBUFFERED

Reads one character at a time from a normally buffered data source, such as a file. Use the UNBUFFERED option only when you can intermingle the input operations of a UNIX process, invoked with the ABL UNIX statement, with the input that follows the ABL INPUT FROM statement.
CONVERT

Allows you to modify the character conversions occurring between the external file and ABL. By default, the INPUT FROM statement converts characters from the code page specified with the Stream Code Page (-cpstream) parameter to the code page specified with the Internal Code Page (-cpinternal) parameter. If you specify SOURCE source-codepage alone, the conversion accepts source-codepage as the code page name of the external file (instead of -cpstream). If you specify TARGET target-codepage, the conversion accepts target-codepage as the internal code page (instead of -cpinternal). If you specify both SOURCE source-codepage and TARGET target-codepage, it converts characters from the source-codepage to target-codepage (instead of -cpstream to -cpinternal).

TARGET target-codepage

Specifies the target code page of the character conversion (replacing -cpinternal). The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management).

SOURCE source-codepage

Specifies the source code page of the character conversion (replacing -cpstream). The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management).

NO-CONVERT

Specifies that no character conversions occur between the external file and memory. By default, the INPUT FROM statement converts characters from the -cpstream code page to the -cpinternal code page.

Example

Instead of getting input from the terminal, this procedure gets input from a file named r-in.dat. The SEARCH function determines the full pathname of this file.

r-in.p

```plaintext
INPUT FROM VALUE(SEARCH("r-in.dat")).

REPEAT:
  FIND Customer USING INPUT Customer.CustNum.
  ASSIGN Customer.CreditLimit.
END.

INPUT CLOSE.
```

This is what the contents of the r-in.dat file look like:

```
1 55800
2 41300
5 88000
```
The PROMPT-FOR statement uses the first data item (1) as the CustNum and the second data item (55800) as the CreditLimit. The FIND statement finds the customer whose CustNum is 1 and assigns the value of 55800 as that Customer’s credit limit. On the next iteration of the REPEAT block, the PROMPT-FOR statement uses the value of 2 as the CustNum, the value of 41300 as the CreditLimit, etc.

The INPUT CLOSE statement closes the input source, reseting it to the terminal. When you run this procedure, the data in the window is simply an echo of the data that the procedure is reading from the taxno.dat file. If you do not want to display the data, add the word NO-ECHO to the end of the INPUT FROM statement.

**Notes**

- To close the current input to a procedure, use the INPUT CLOSE statement. (The input source is automatically closed at the end of the procedure or when another default input source is opened.)

- The BINARY option allows you to use the READKEY statement to read control characters from the input source without interpretation. For example, NUL (\0) does not terminate strings, CTRL+Z does not signal EOF, and CTRL+J is not converted to CTRL+M, but their binary values are provided directly.

- If the input source and output destination are both the TERMINAL, then ECHO is always in effect.

- Use the IMPORT, INSERT, PROMPT-FOR, SET, or UPDATE statements to read data into an ABL procedure. The data is placed into the frame fields referenced in these statements, and, if you use ECHO, then the frame is output to the current output destination. If you use the NO-ECHO option, then the frame is not output. If a subsequent DISPLAY statement causes the frame to appear, then the input data also appears if the frame is not yet in view.

- SEEK is not supported in conjunction with the OS-DIR option.

- When using the OS-DIR option, the UNBUFFERED option is ignored. OS-DIR  always buffers exactly one filename at a time.

- If you use the PROMPT-FOR, SET, or UPDATE statement to read data from a file, the FORMAT for the data is ignored. Therefore, if you rely on FORMAT to validate input, you might read invalid characters.

- If you use the PROMPT-FOR, SET, or UPDATE statement to read data from a file, and there is a piece of data in each line of the file that you want to disregard, use a caret (^) in the PROMPT-FOR, SET, or UPDATE statement. For more information on this symbol, see the reference entry for any of those statements.

- If end of file is reached, the AVM responds as if you pressed ENDKEY.

- If a line consisting of a single period is read, that is treated as if you pressed END-ERROR. If the period is in quotes ("." ) it is treated as an ordinary character.

- When you use the INPUT FROM statement to read data from a file, there are two special characters you can use in that data file: tilde (~) and (slash (/) on UNIX, and hyphen (-). If characters in an input file take up more than one physical line, you can use tilde (~) to indicate a line continuation. This is an input file that uses a tilde:
Do not include a space after the tilde. For example:

<table>
<thead>
<tr>
<th>Cust-num</th>
<th>Name</th>
<th>Address</th>
<th>City</th>
<th>State</th>
<th>Code</th>
</tr>
</thead>
<tbody>
<tr>
<td>92</td>
<td>Match Point Tennis</td>
<td>66 Homer Ave</td>
<td>Como</td>
<td>TX</td>
<td>75431</td>
</tr>
<tr>
<td>93</td>
<td>Off The Wall</td>
<td>20 Leedsville Ave</td>
<td>Export</td>
<td>PA</td>
<td>15632</td>
</tr>
</tbody>
</table>

- You can see that the record containing the tilde was treated as a single input line.
- A hyphen in an input file indicates that you do not want to change the corresponding field in the INSERT, PROMPT-FOR, SET or UPDATE statement. This is the same input file as shown above, including the hyphen:

<table>
<thead>
<tr>
<th>Cust-num</th>
<th>Name</th>
<th>Address</th>
<th>City</th>
<th>State</th>
<th>Code</th>
</tr>
</thead>
<tbody>
<tr>
<td>92</td>
<td>Match Point Tennis</td>
<td>-</td>
<td>Como</td>
<td>TX</td>
<td>75431</td>
</tr>
<tr>
<td>93</td>
<td>Off the Wall</td>
<td>20 Leedsville Ave</td>
<td>Export</td>
<td>PA</td>
<td>15632</td>
</tr>
</tbody>
</table>

The procedure in the following example uses this file to set records in the customer file. When those records are displayed, the Match Point Tennis address does not change.

<table>
<thead>
<tr>
<th>Cust-num</th>
<th>Name</th>
<th>Address</th>
<th>City</th>
<th>State</th>
<th>Code</th>
</tr>
</thead>
<tbody>
<tr>
<td>92</td>
<td>Match Point Tennis</td>
<td>-</td>
<td>Como</td>
<td>TX</td>
<td>75431</td>
</tr>
<tr>
<td>93</td>
<td>Off The Wall</td>
<td>20 Leedsville Ave</td>
<td>Export</td>
<td>PA</td>
<td>15632</td>
</tr>
</tbody>
</table>

To enter a literal hyphen from a file, enclose it in quotes ("-").

- In Windows, the data in the input file must have the following characteristics:
  - The lines of data in the file are separated by CR-LF pairs.
  - There is no `CTRL+Z` (EOF) embedded in the file.
- For any character conversions to occur, all of the necessary conversion tables must appear in `convmap.cp` (a binary file that contains all of the tables that ABL uses for character management).
- If you specify a value of “undefined” for either `source-codepage` or `target-codepage`, no character conversion is performed.
- If the field being input is MEMPTR, you must use the BINARY and NO-CONVERT mode of operation to prevent your data from becoming corrupted if it contains binary data.
- With the BINARY and NO-CONVERT options, you will not get a translation of new-lines to the appropriate characters for your operating system and there will be no code page conversion between `-cpinternal` and `-cpstream.`
• If the field being input is MEMPTR and your MEMPTR contains ASCII data you may want code page conversion. However, you cannot get conversion by using the CONVERT parameter on the MEMPTR. You can get code page conversion by using the MEMPTR with the GET-STRING and CODEPAGE-CONVERT functions and the PUT-STRING statement.

See also
DEFINE STREAM statement, INPUT CLOSE statement, INPUT THROUGH statement, Stream object handle

INPUT THROUGH statement

Uses the output from a program as the input to an ABL procedure.

Syntax

```
INPUT [ STREAM stream ] [ STREAM-HANDLE handle ] THROUGH
{ program-name  | VALUE ( expression ) }
{ argument      | VALUE ( expression ) } ...
[ ECHO          | NO-ECHO ]
[ MAP protermcap-entry | NO-MAP ]
[ UNBUFFERED ]
[ NO-CONVERT
  | { CONVERT
  [ TARGET target-codepage ]
  [ SOURCE source-codepage ]
  }
]
```

STREAM stream

Specifies the name of a stream. If you do not name a stream, the unnamed stream is used. See the DEFINE STREAM statement reference entry and OpenEdge Development: Programming Interfaces for more information on streams.

STREAM-HANDLE handle

Specifies the handle to a stream. If handle it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams and stream handles.

program-name

Represents the name of the UNIX program where you are supplying data to an ABL procedure. This can be a standard UNIX command or your own program.

VALUE ( expression )

Specifies an expression whose value is the name of a UNIX program where you are supplying data to an ABL procedure.

Or, it is an expression whose value is an argument you want to pass to the UNIX program. INPUT THROUGH passes the value of expression as a character string.
**INPUT THROUGH statement**

`argument`

Represents an argument you want to pass to the UNIX program. INPUT THROUGH passes this `argument` as a character string.

If the `argument` is the literal value `echo`, `no-echo`, or `unbuffered`, enclose it in quotes to prevent the AVM from interpreting that argument as one of the ECHO, NO-ECHO, or UNBUFFERED options for the INPUT THROUGH statement.

**ECHO**

Displays all input data on the current output destination. Data is echoed by default.

**NO-ECHO**

Accepts input data without displaying it on the current output device.

**MAP protermcap-entry | NO-MAP**

The `protermcap-entry` value is an entry from the PROTERMCAP file. Use MAP to read an input stream that uses a different character translation from the current stream. Typically, `protermcap-entry` is a slash-separated combination of a standard device entry and one or more language-specific add-on entries (MAP laserwriter/french or MAP hp2/spanish/italian, for example). The AVM uses the PROTERMCAP entries to build a translation table for the stream. Use NO-MAP to make the AVM bypass character translation altogether. See *OpenEdge Deployment: Managing ABL Applications* for more information on PROTERMCAP. See *OpenEdge Development: Internationalizing Applications* for more information on national language support.

**UNBUFFERED**

Reads one character at a time from a normally buffered data source, such as a file. Use the UNBUFFERED option only when the input operations of a UNIX process invoked by the ABL UNIX statement might be intermingled with the input from the ABL statements that follow the INPUT THROUGH statement.

**CONVERT**

Allows you to modify the character conversions occurring between the UNIX program and ABL. By default, the INPUT THROUGH statement converts characters from the code page specified with the Stream Code Page (-cpstream) parameter to the code page specified with the Internal Code Page (-cpinternal) parameter. If you specify `SOURCE source-codepage` alone, the conversion accepts `source-codepage` as the code page name of the UNIX program (instead of -cpstream). If you specify `TARGET target-codepage`, the conversion accepts `target-codepage` as the internal code page (instead of -cpinternal). If you specify both `SOURCE source-codepage` and `TARGET target-codepage`, it converts characters from the `source-codepage` to `target-codepage` (instead of -cpstream to -cpinternal).

**TARGET target-codepage**

Specifies the target code page of the character conversion (replacing -cpinternal). The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management).
SOURCE  target-codepage

Specifies the source code page of the character conversion (replacing -cpstream). The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management).

NO-CONVERT

Specifies that no character conversions occur between the UNIX program and ABL. By default, the INPUT THROUGH statement converts characters from the -cpstream code page to the -cpinternal code page.

Examples

This procedure uses as its input source the output of the UNIX echo command. Before the command runs, the UNIX shell substitutes the process-id number for $$ and the current directory search path for $PATH. The results are then echoed and become available as a line of input to ABL. When the IMPORT statement is executed, the line of input from echo is read and the values are assigned to the two variables. Those variables can then be used for any purpose. In this example, the word echo must be lowercase and the word $PATH must be uppercase, since they both pass to UNIX:

r-thru.p

```
DEFINE VARIABLE process-id AS CHARACTER NO-UNDO.
DEFINE VARIABLE dir-path  AS CHARACTER NO-UNDO
   VIEW-AS EDITOR SIZE 60 BY 10.

INPUT THROUGH echo $$ $PATH NO-ECHO.

SET process-id dir-path WITH FRAME indata NO-BOX NO-LABELS.
DISPLAY process-id dir-path FORMAT "x(70)".

INPUT CLOSE.
```

When you use INPUT THROUGH, the UNIX program you name is executed as a separate process under its own shell. Therefore, the values of shell variables (such as $$) are values from that shell rather than the shell from which the AVM executes.

The following procedure uses INPUT THROUGH twice to get input from the UNIX pwd and ls commands. The pwd command supplies the name of the current directory and the ls command supplies the name of each UNIX file in your current directory. After the variable fn is set, it displays on the screen.
INPUT-OUTPUT CLOSE statement

Closes a specified or default stream opened by an INPUT-OUTPUT THROUGH statement.

Syntax

```
INPUT-OUTPUT [ STREAM stream | STREAM-HANDLE handle ] CLOSE
```
STREAM stream

The name of the stream you want to close. If you do not name a stream, the AVM closes the default stream used by an INPUT-OUTPUT THROUGH statement.

STREAM-HANDLE handle

The handle to the stream you want to close. If you do not specify the handle, the AVM closes the default stream used by an INPUT-OUTPUT THROUGH statement.

Example

This procedure uses a C program to recalculate the price of each item in inventory. Specifically, the C program increases the price of each item by 3% or by 50 cents, whichever is greater. The INPUT-OUTPUT THROUGH statement tells the procedure to get its input from, and send its output to, the r-iothru.p procedure. The INPUT-OUTPUT CLOSE statement resets the input source to the terminal and the output destination to the terminal.

r-iothru.p

```c
FOR EACH Item NO-LOCK WHERE Item.ItemNum < 10:
    DISPLAY Item.ItemNum Item.Price LABEL "Price before recalculation".
END.

INPUT-OUTPUT THROUGH r-iothru UNBUFFERED.

FOR EACH Item WHERE Item.ItemNum < 10:
    EXPORT Item.Price.
    SET Item.Price.
END.

INPUT-OUTPUT CLOSE.

FOR EACH Item WHERE Item.ItemNum < 10 WITH COLUMN 40:
    DISPLAY Item.ItemNum Item.Price LABEL "Price after recalculation".
END.
```

Note

For more information, see OpenEdge Development: Programming Interfaces.

See also

DEFINE STREAM statement, INPUT-OUTPUT THROUGH statement, Stream object handle

INPUT-OUTPUT THROUGH statement

Names a program (process) for the AVM to start. This process is the input source as well as the output destination for the procedure.
INPUT-OUTPUT THROUGH statement

Syntax

```plaintext
INPUT-OUTPUT [ STREAM stream | STREAM-HANDLE handle ]
THROUGH { program-name | VALUE ( expression ) }
[ argument | VALUE ( expression ) ] ...  
[ ECHO | NO-ECHO ]
[ MAP protermcap-entry | NO-MAP ]
[ UNBUFFERED ]
[ NO-CONVERT
  | { CONVERT
    [ TARGET target-codepage ]
    [ SOURCE source-codepage ]
  ]
]
```

STREAM stream

Specifies the name of a stream. If you do not name a stream, the unnamed stream is used. See the `DEFINE STREAM` statement reference entry and *OpenEdge Development: Programming Interfaces* for more information on streams.

STREAM-HANDLE handle

Specifies the handle to a stream. If `handle` it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in *OpenEdge Development: Programming Interfaces* for more information on streams and stream handles.

program-name

Identifies the name of the UNIX program where the procedure is getting data and where the procedure is sending data.

VALUE ( expression )

Represents an expression whose value is the name of a UNIX program where the procedure is getting data and where the procedure is sending data.

Or, it is an expression whose value is an argument you want to pass to the UNIX program. INPUT-OUTPUT THROUGH passes the value of `expression` as a character string.

argument

Specifies an argument you want to pass to the UNIX program. INPUT-OUTPUT THROUGH passes this argument as a character string.

If the argument is the literal value echo, no-echo, or unbuffered, you must enclose it in quotes to prevent the AVM from interpreting that argument as one of the ECHO, NO-ECHO, or UNBUFFERED options for the INPUT-OUTPUT THROUGH statement.

ECHO

Displays all input data to the unnamed stream. Data is not echoed by default.
NO-ECHO

Accepts input data without displaying it on the current unnamed stream. Data is not echoed by default.

MAP protermcap-entry | NO-MAP

The protermcap-entry value is an entry from the PROTERMCAP file. MAP allows you to send output to and receive input from an I/O stream that uses different character translation than the current stream. Typically, protermcap-entry is a slash-separated combination of a standard device entry and one or more language-specific add-on entries (MAP laserwriter/french or MAP hp2/spanish/italian, for example). The AVM uses the PROTERMCAP entries to build a translation table for the stream. Use NO-MAP to make the AVM bypass character translation altogether. See OpenEdge Deployment: Managing ABL Applications for more information on PROTERMCAP. See OpenEdge Development: Internationalizing Applications for more information on national language support.

UNBUFFERED

Reads and writes one character at a time from a normally buffered data source, such as a file. Use the UNBUFFERED option only when the input-output operations of a process invoked by ABL’s UNIX statement can be intermingled with the input-output from the ABL statements that follow the INPUT-OUTPUT THROUGH statement. INPUT-OUTPUT THROUGH handles the buffering of data between the ABL procedure and the UNIX program that it invokes. Use the UNBUFFERED option if your procedure invokes any other programs with the UNIX statement.

CONVERT

Allows you to modify the character conversions occurring between the UNIX program and ABL. By default, the INPUT-OUTPUT THROUGH statement converts characters from the Stream Code Page (-cpstream) parameter to the code page specified with the Internal Code Page (-cpinternal) parameter as data received from program-name. As data is passed to program-name, then INPUT-OUTPUT THROUGH converts from the -cpinternal to -cpstream. If you specify SOURCE source-codepage alone, the conversion accepts source-codepage as the code page name of the UNIX program (instead of -cpstream). If you specify TARGET target-codepage, the conversion accepts target-codepage as the internal code page (instead of -cpinternal). If you specify both SOURCE source-codepage and TARGET target-codepage, it converts characters from the source-codepage to target-codepage (instead of -cpstream to -cpinternal).

TARGET target-codepage

Specifies the target code page of the character conversion (replacing -cpinternal). The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management).

SOURCE source-codepage

Specifies the source code page of the character conversion (replacing -cpstream). The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management).
NO-CONVERT

Specifies that no character conversions occur between the UNIX program and ABL. By default, the INPUT-OUTPUT THROUGH statement converts characters from the -cpstream code page to the -cpinternal code page as data is received from program-name. As data is passed to program-name, then INPUT-OUTPUT THROUGH converts from the -cpinternal to -cpstream.

Examples

This procedure uses a C program to recalculate the price of each item in inventory. Specifically, the C program increases the price of each item by 3% or by 50 cents, whichever is greater. The INPUT-OUTPUT THROUGH statement tells the procedure to get its input from, and send its output to, the r-iothru.p procedure. The INPUT-OUTPUT CLOSE statement resets the input source to the terminal and the output destination to the terminal.

r-iothru.p

```c
FOR EACH Item WHERE Item.ItemNum < 10:
    DISPLAY Item.ItemNum Item.Price LABEL "Price before recalculation".
END.

INPUT-OUTPUT THROUGH r-iothru UNBUFFERED.

FOR EACH Item WHERE Item.ItemNum < 10:
    EXPORT Item.Price.
    SET Item.Price.
END.

INPUT-OUTPUT CLOSE.

FOR EACH Item WHERE Item.ItemNum < 10 WITH COLUMN 40:
    DISPLAY Item.ItemNum Item.Price LABEL "Price after recalculation".
END.
```

You can perform this calculation within a single ABL procedure. The C program is used for illustration purposes only. Use a UNIX program outside ABL to execute specialized calculations or processing.

You must unpack the C program from the proguide subdirectory and compile it before you can use it with the r-iothru.p procedure. If you do not have a C compiler, do not try this example.

Following is the C program used by the r-iothru.p procedure:
**Notes**

- Use **EXPORT** or **PUT**, not **DISPLAY**, to write data to the program.

- Use **SET** to read data from the program.

- If you read data from a C program, put an upper limit on how many errors can occur before the program ends. Also remember that if the program prints an error message, that message is sent to ABL as data. You can use `fprintf(stderr,...)` to display debugging messages to the window, even in the middle of an **INPUT-OUTPUT THROUGH** operation.

- With **INPUT-OUTPUT THROUGH** in non-interactive mode, an ABL procedure can send information to a UNIX program, and the program can process that information and send the results back to the AVM. Some UNIX utilities you can use in batch mode are `wc` (word count) and `sort`.

Here are some pointers for using **INPUT-OUTPUT THROUGH** in this way:

  - When the procedure finishes sending data to the program, use the **OUTPUT CLOSE** statement to reset the standard output stream to the screen. Doing this signals an EOF on the pipe, indicating that the program has received all input. When the procedure has received all data from the program, use the **INPUT CLOSE** statement to reset the standard input stream. Do not use the **INPUT-OUTPUT CLOSE** statement, because that closes both pipes at once.

  - If you want to use the **INPUT-OUTPUT THROUGH** statement with a UNIX utility that buffers its output, use the non-interactive approach.

  - To signal an EOF, use **OUTPUT CLOSE** (rather than attempting to send a **CTRL+D**).

When you use **INPUT-OUTPUT THROUGH** in interactive mode the AVM sends data to the program, and the program sends data back to the AVM, etc.

Here are some pointers for using **INPUT-OUTPUT THROUGH** in this way:

  - At the end of the interaction between the procedure and the program, use the **INPUT-OUTPUT CLOSE** statement to shut down both pipes.
Be sure that the program you are using does not buffer its output. If the program is a C program, the first line of the program should be “setbuf(stdout, (char *) NULL);”. The program should also include “#include <stdio.h>”. These tell UNIX that the standard output of the program is unbuffered. If the program does buffer its output, use the batch approach to INPUT-OUTPUT THROUGH as explained in the previous note.

If the program ends on some condition other than detecting an EOF, make sure that it tells the ABL procedure that it is about to end.

• For any character conversions to occur, all of the necessary conversion tables must appear in convmap.cp (a binary file that contains all of the tables that ABL uses for character management).

• If you specify a value of “undefined” for either source-codepage or target-codepage, no character conversion is performed.

See also  DEFINE STREAM statement, INPUT CLOSE statement, INPUT-OUTPUT CLOSE statement, Stream object handle

## INSERT statement

Creates a new database record, displays the initial values for the fields in the record, prompts for values of those fields, and assigns those values to the record.

The INSERT statement is a combination of the following statements:

• **CREATE** — Creates an empty record buffer

• **DISPLAY** — Moves the record from the record buffer into the screen buffer and displays the contents of the buffer on the screen

• **PROMPT-FOR** — Accepts input from the user, and puts that input into the screen buffer

• **ASSIGN** — Moves data from the screen buffer into the record buffer

**Note:** Does not apply to SpeedScript programming.

### Data movement

1. **CREATE** — Creates an empty record buffer
2. **DISPLAY** — Moves the contents of the record buffer to the screen buffer and displays the screen buffer

3. **PROMPT-FOR** — Accepts input from the user into the screen buffer

4. **ASSIGN** — Moves the contents of the screen buffer to the record buffer

**Syntax**

```
INSERT record [ EXCEPT field ... ]
[ USING { ROWID ( nrow ) | RECID ( nrec ) } ]
[ frame-phrase ]
[ NO-ERROR ]
```

**record**

The name of the record you want to add to a database file. The AVM creates one record buffer for every file you use in a procedure. This buffer is used to hold a single record from the file associated with the buffer. Use the DEFINE BUFFER statement to create additional buffers, if necessary. The CREATE part of the INSERT statement creates an empty record buffer for the file in which you are inserting a record.

To insert a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

**EXCEPT field**

Inserts all fields except those listed in the EXCEPT phrase.

**USING { ROWID ( nrow ) | RECID ( nrec ) }**

Allows you to insert a record in an RMS relative file (for backward compatibility only) using a specific record number, where nrow is the ROWID relative record number of the record you want to insert and nrec is the RECID relative record number of the record you want to insert.

**frame-phrase**

Specifies the overall layout and processing properties of a frame. For more information on frame-phrase, see the Frame phrase reference entry.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.
• Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

• Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

• NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

• A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

• When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

• If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

Example

In this procedure the user adds a new Order record. After the user adds a new Order record, the procedure creates OrderLines for that record. The procedure uses the CREATE statement to create OrderLines rather than the INSERT statement. When you use the INSERT statement, the PROMPT-FOR and ASSIGN parts of the INSERT let you put data into all the fields of the record being inserted. In the case of OrderLines, this procedure only lets you add information into a few of the OrderLine fields. Use CREATE together with UPDATE to single out the OrderLine fields.
INT64 function

Takes any data type and returns an INT64 value, if the conversion is possible. This function takes most common data types except for RAW and MEMPTR.

Syntax

```
INT64 ( expression )
```
**INTEGER function**

A constant, field name, variable name, or expression whose value can be of any data type except for RAW and MEMPTR. If the value of expression is a CHARACTER, it must be valid for conversion into a number (for example, “1.67” is valid, “1.x3” is not). If expression is an object reference (CLASS), the result is the ABL-generated ID for the class instance. If expression is a LOGICAL, the result is 0 if expression is FALSE and the result is 1 if expression is TRUE. If expression is a DATE, the result is the number of days from 1/1/4713 B.C. to that day. If expression is the Unknown value (?), the result is the Unknown value (?).

**Example**

The following example demonstrates how to use the INT64 function to convert a variety of data types to the INT64 data type:

```abl
DEFINE VARIABLE myint AS INTEGER NO-UNDO INITIAL 2000000000 FORMAT "->>,>>>,>>>,>>>".
DEFINE VARIABLE myint64 AS INT64 NO-UNDO INITIAL 33344555666 FORMAT "->>,>>>,>>>,>>>,>>>".
DEFINE VARIABLE mychar AS CHARACTER NO-UNDO INITIAL "2234.3".
DEFINE VARIABLE mydec AS DECIMAL NO-UNDO INITIAL "240,234.05".
DEFINE VARIABLE mybool AS LOGICAL NO-UNDO INITIAL TRUE.
DEFINE VARIABLE mydate AS DATE NO-UNDO INITIAL 01/01/06.
DEFINE VARIABLE myhdl AS HANDLE NO-UNDO.

DEFINE FRAME x WITH TITLE "emptyframe".
myhdl = FRAME x:handle.

MESSAGE "integer of integer expression is" INTEGER(myint).
MESSAGE "integer of int64 expression is" INTEGER(myint64).
MESSAGE "integer of char is" INTEGER(mychar).
MESSAGE "integer of dec is" INTEGER(mydec).
MESSAGE "integer of bool is" INTEGER(mybool).
MESSAGE "integer of date is" INTEGER(mydate).
MESSAGE "integer of handle is" INTEGER(myhdl).
MESSAGE "".

MESSAGE "int64 of integer expression is" INT64(myint).
MESSAGE "int64 of int64 expression is" INT64(myint64).
MESSAGE "int64 of char is" INT64(mychar).
MESSAGE "int64 of dec is" INT64(mydec).
MESSAGE "int64 of bool is" INT64(mybool).
MESSAGE "int64 of date is" INT64(mydate).
MESSAGE "int64 of handle is" INT64(myhdl).
MESSAGE "".
```

**See also**

GET-INT64 function, PUT-INT64 statement, INTEGER function, DECIMAL function, STRING function

**INTEGER function**

Converts an expression of any data type, with the exception of BLOB, CLOB, and RAW, to a 32-bit integer value of data type INTEGER, rounding that value if necessary.
expression

A constant, field name, variable name, or expression. If the value of expression is a CHARACTER, it must be valid for conversion into a number (for example, “1.67” is valid, “1.x3” is not). If expression is an object reference (CLASS), the result is the ABL-generated ID for the class instance. If expression is a LOGICAL, the result is 0 if expression is FALSE and the result is 1 if expression is TRUE. If expression is a DATE, the result is the number of days from 1/1/4713 B.C. to that day. If expression is the Unknown value (?), the result is the Unknown value (?).

Example

This procedure takes the first word (that is, the substring that precedes the first space character) from the Customer Address and tries to convert it to an integer (street-number). If the conversion fails (for example, the first word contains non-numeric characters) the procedure displays an error message. Otherwise the CustNum, Address, and converted street number are displayed.

```
DEFINE VARIABLE street-number AS INTEGER NO-UNDO LABEL "Street Number".
FOR EACH Customer NO-LOCK:
ASSIGN street-number = INTEGER(ENTRY(1, Customer.Address, " ")) NO-ERROR.
IF ERROR-STATUS:ERROR THEN
   MESSAGE "Could not get street number of" Customer.Address.
ELSE
END.
```

DECIMAL function, STRING function

INTERFACE statement

Defines a user-defined interface. An interface defined with this statement represents a user-defined data type that defines a set of method, property, and event prototypes for methods, properties, and events that can be implemented by one or more classes. Any class that implements the interface must support all the methods, properties, and events whose prototypes are defined in the interface.

You cannot instantiate an interface as an object. You can only use it to define the specified interface for a class (which you can instantiate) that implements the interface.

Note: This statement is applicable only when used in a class definition (.cls) file. For more information, see the Notes section in this reference entry.

Syntax

```
INTERFACE interface-type-name :
interface-body
```
INTERFACE statement

**interface-type-name**

Defines the type name for a user-defined interface type. Specify an ABL interface type name as described in the Type-name syntax reference entry. You can also specify an unqualified interface name (without a package), but only if the interface name represents the full type name for the interface (that is, the interface is not defined as part of a package).

Note that you cannot specify "Progress" as the first component of the package name for any ABL user-defined interface. For example, "Progress.Inventory.IUpdateInv" is an invalid type name for a user-defined interface and results in a compiler error.

**interface-body**

The body of an interface definition is composed of the following types of elements:

- Temp-table or ProDataSet object definitions used as parameters by one or more methods whose prototype is declared in this interface
- Method prototypes for common methods implemented by one or more classes
- Property prototypes for common properties implemented by one or more classes
- Event prototypes for common events implemented by one or more classes

Define elements in the interface body using the following syntax:

**Syntax**

```
[ { temp-table | dataset } ... ]
[ method-prototypes ]
[ property-prototypes ]
[ event-prototypes ]
END [ INTERFACE ].
```

**temp-table | dataset**

Specifies one or more temp-table or ProDataSet object definitions used as parameters by one or more methods declared in this interface. You must specify these object definitions before any method prototypes. The AVM does not allocate memory for these object definitions. You cannot specify an access mode for these object definitions.

The definition of temp-table and ProDataSet object parameters for methods defined in any classes that implement this interface must match the temp-table or ProDataSet object definitions in this interface.

For temp-table objects:

- The temp-tables must have the same number of fields, and each field must match with respect to the data type, extent, and position. Neither the table names nor field names must match.
• The temp-tables must have the same number of indexes, and each index component must match, including the index names. However, the index-component field names do not need to match.

For ProDataSet objects:

• The ProDataSet objects must have the same number of member buffers, and the buffers must be in the same order. Neither the buffer names nor ProDataSet names must match.

• The temp-tables of these buffers must match as described above.

**method-prototypes**

Declares one or more method prototypes in the interface. A method prototype declares a method of a class without an implementation (that is, without specifying the method’s logic or the END METHOD statement).

For information on the syntax for `method-prototype`, see the METHOD statement reference entry for declaring method prototypes. Note the following:

• The method access mode must be PUBLIC, either explicitly declared or defaulted.

• The method prototype must not include the STATIC, ABSTRACT, OVERRIDE, or FINAL options.

The implementation of these method prototypes, in classes that implement this interface, must not include the STATIC option and must match these declarations with respect to:

• Access mode, which must be PUBLIC

• Return type

• The number, data type, and access mode of any parameters

**property-prototypes**

Declares one or more property prototypes in the interface. A property prototype declares a property of a class without implementing its GET or SET accessors (that is, without specifying the property’s logic). You must specify a property prototype with a PUBLIC access mode. The property prototype must include either a GET and SET accessor, or a GET accessor, or a SET accessor. Although the property declaration cannot have accessor implementations, the property when implemented in a class may include an accessor implementation.

For information on the syntax for `property-prototype`, see the DEFINE PROPERTY statement reference entry for declaring property prototypes. Note the following:

• The property access mode must be PUBLIC, either explicitly declared or defaulted.

• The property prototype must not include the STATIC, ABSTRACT, OVERRIDE, or INITIAL options.
• Accessors must not include access modifiers.
• Accessors must not include implementations.

The implementation of the property, in classes that implement this interface, must not include the STATIC option and must match these declarations with respect to:

• Access mode, which must be PUBLIC
• Name
• Data type or type name
• EXTENT — Its presence or absence, determinate or indeterminate, and size (if determinate)
• Accessors — Any accessor appearing in the interface, plus the option of any additional accessor not specified in the interface, all defaulting to PUBLIC access mode
• Presence or absence of NO-UNDO

event-prototypes

Declares one or more event prototypes in the interface. An event prototype declares a class event that the class must implement with an identical declaration, allowing the class to publish the event.

For information on the syntax for event-prototype, see the DEFINE EVENT statement reference entry for declaring class event prototypes. Note the following:

• The event access mode must be PUBLIC, either explicitly declared or defaulted.
• The event prototype must not include the STATIC, ABSTRACT, or OVERRIDE options.

The implementation of these event prototypes, in classes that implement this interface, must not include the STATIC option and must match these declarations with respect to:

• Access mode, which must be PUBLIC
• Any specified .NET delegate type or the number, data type, and access mode of any specified parameters

END [ INTERFACE ]

Specifies the end of the interface body definition. You must end the interface body definition with the END statement.

Examples

The following samples include two different class definitions that provide similar functionality, but in distinctly different ways. Each class implements the same interface and both classes define a ProDataSet data member (dsHighCustData) used to retrieve Customer and related Invoice table data for a single Customer record from the sports2000 database. However, each class selects the Customer record using a different and functionally distinct algorithm provided in its own implementation of the same interface method prototype.
Thus, each of the following sample class files implements the r-ICustObj interface type defined in the class definition file, r-ICustObj.cls and provides the following functionality:

1. r-ICustObjImp1.cls — Defines the r-ICustObjImp1 class, which retrieves data from the single Customer and related Invoice records that contain the highest balance value represented by the Customer.Balance value. This functionality is almost identical to what is provided by the r-CustObj.cls sample class file that is fully described in the Examples section of the CLASS statement reference entry. (The main differences from the r-ICustObjImp1 class are that the r-CustObj class does not implement an interface type and it is defined as FINAL.)

2. r-ICustObjImp12.cls — Defines the r-ICustObjImp12 class, which also retrieves data from a single Customer and related Invoice records. However, this class retrieves data for the Customer whose related Invoice records contain the highest Invoice balance represented by the sum of their Invoice.Amount values.

Following is the interface definition provided by the sample r-ICustObj.cls file.

r-ICustObj.cls

```
INTERFACE r-ICustObj:
/* Property prototypes to return basic values for the Customer identified with the highest balance in the database */
DEFINE PUBLIC PROPERTY HighCustBalance AS DECIMAL NO-UNDO
  GET.
  SET.
DEFINE PUBLIC PROPERTY HighCustNum AS INTEGER NO-UNDO
  GET.
  SET.

/* Event prototype to notify about Customers with Invoices */
DEFINE PUBLIC EVENT CustHasInvoices
  SIGNATURE VOID ( piCustNum AS INTEGER ).

/* Temp-tables for the ProDataSet parameter */
DEFINE TEMP-TABLE ttCust NO-UNDO LIKE Customer.
DEFINE TEMP-TABLE ttInv NO-UNDO LIKE Invoice.

/* ProDataSet parameter for passing a single Customer with the highest balance along with its related Invoices */
DEFINE DATASET dsHighCustData FOR ttCust, ttInv
  DATA-RELATION FOR ttCust, ttInv
  RELATION-FIELDS (ttCust.CustNum, ttInv.CustNum).

/* Method prototype to get the current high Customer balance data */
METHOD PUBLIC VOID GetHighCustomerData
  ( OUTPUT DATASET dsHighCustData BIND ).

/* Method prototype to set (or reset) the current high Customer data */
METHOD PUBLIC VOID SetHighCustomerData () .
END INTERFACE.
```
The implementations of the SetHighCustomerData( ) method populate the ProDataSet with selected fields from Customer and Invoice records, where the selected Customer also has related invoices. Each implementation of SetHighCustomerData( ) also sets the two implemented properties (HighCustBalance and HighCustNum) to appropriate values for the selected Customer, and publishes the implemented class event (CustHasInvoices) for each Customer record it encounters with related Invoice records. Each class defines additional data members to support its instance of the ProDataSet, and also must implement the GetHighCustomerData( ) method (according to the interface) to pass the ProDataSet as a by-reference output parameter.

Following is the interface implementation provided by the r-ICustObjImpl sample class. Note that the property implementations add initial values, but rely on default behavior for the accessors. The class also fully defines the ProDataSet to be passed as a by-reference method output parameter.

r-ICustObjImpl.cls

CLASS r-ICustObjImpl IMPLEMENTS r-ICustObj:

/* Public properties to return basic values for a customer with the highest balance */
DEFINE PUBLIC PROPERTY HighCustBalance AS DECIMAL INITIAL 0.0 NO-UNDO
  GET.
  SET.
DEFINE PUBLIC PROPERTY HighCustNum AS INTEGER INITIAL ? NO-UNDO
  GET.
  SET.

/* Public event to notify about Customers with Invoices */
DEFINE PUBLIC EVENT CustHasInvoices
  SIGNATURE VOID ( piCustNum AS INTEGER ).

/* Private handle variable for the high customer ProDataSet */
DEFINE PRIVATE VARIABLE hHighCustData AS HANDLE NO-UNDO.

/* Private temp-tables for the high customer ProDataSet */
DEFINE PRIVATE TEMP-TABLE ttCust NO-UNDO LIKE Customer.
DEFINE PRIVATE TEMP-TABLE ttInv NO-UNDO LIKE Invoice.

/* Private ProDataSet for a single customer with the highest balance and its invoices */
DEFINE PRIVATE DATASET dsHighCustData FOR ttCust, ttInv
  DATA-RELATION FOR ttCust, ttInv
  RELATION-FIELDS (ttCust.CustNum, ttInv.CustNum).

/* Private query and data sources for the ProDataSet */
DEFINE PRIVATE QUERY qCust FOR Customer.
DEFINE PRIVATE DATA-SOURCE srcCust FOR QUERY qCust.
DEFINE PRIVATE DATA-SOURCE srcInv FOR Invoice.

/* Constructor to initialize handles and attach data sources */
CONSTRUCTOR r-ICustObjImpl ( ):

  hHighCustData = DATASET dsHighCustData:HANDLE.
  BUFFER ttInv:ATTACH-DATA-SOURCE( DATA-SOURCE srcInv:HANDLE ).

END CONSTRUCTOR.
The bold code inside the `SetHighCustomerData()` method shows the difference in implementation from the same method implemented by the following `r-ICustObjImpl2` sample class. Here, it relies on the stored value of the `Customer.Balance` field to determine each `Customer` balance and assigns the `HighCustBalance` and `HighCustNum` property values accordingly.

The following `r-ICustObjProc.p` sample procedure shows an application of the `r-ICustObjImpl` class, which responds to the `CustHasInvoices` class event and displays the contents of the `dsHighCustCata` ProDataSet. Note that it defines a reference-only instance of the `ProDataSet` as required by the class and its interface. (This application is identical to the `r-CustObjProc.p` sample procedure described in the Examples section of the `CLASS statement`, but which instantiates the `r-CustObj` sample class instead.)
Following is the interface implementation provided by the r-ICustObjImpl2 sample class. This implementation is identical to r-ICustObjImpl except for the SetHighCustomerData( ) method.
CLASS r-ICustObjImpl2 IMPLEMENTS r-ICustObj:

/* Public properties to return basic values for a customer with the highest balance */
DEFINE PUBLIC PROPERTY HighCustBalance AS DECIMAL INITIAL 0.0 NO-UNDO
  GET.
  SET.
DEFINE PUBLIC PROPERTY HighCustNum AS INTEGER INITIAL ? NO-UNDO
  GET.
  SET.

/* Public event to notify about Customers with Invoices */
DEFINE PUBLIC EVENT CustHasInvoices
  SIGNATURE VOID ( piCustNum AS INTEGER ).

/* Private handle variable for the high customer ProDataSet */
DEFINE PRIVATE VARIABLE hHighCustData AS HANDLE NO-UNDO.

/* Private temp-tables for the high customer ProDataSet */
DEFINE PRIVATE TEMP-TABLE ttCust NO-UNDO LIKE Customer.
DEFINE PRIVATE TEMP-TABLE ttInv NO-UNDO LIKE Invoice.

/* Private ProDataSet for a single customer with the highest balance and its invoices */
DEFINE PRIVATE DATASET dsHighCustData FOR ttCust, ttInv
  DATA-RELATION FOR ttCust, ttInv
  RELATION-FIELDS (ttCust.CustNum, ttInv.CustNum).

/* Private query and data sources for the ProDataSet */
DEFINE PRIVATE QUERY qCust FOR Customer.
DEFINE PRIVATE DATA-SOURCE srcCust FOR QUERY qCust.
DEFINE PRIVATE DATA-SOURCE srcInv FOR Invoice.

/* Constructor to initialize handles and attach data sources */
CONSTRUCTOR r-ICustObjImpl2 ( ):
  hHighCustData = DATASET dsHighCustData:HANDLE.
  BUFFER ttInv:ATTACH-DATA-SOURCE( DATA-SOURCE srcInv:HANDLE ).
END CONSTRUCTOR.
The bold code inside the SetHighCustomerData() method shows the difference in implementation from the same method implemented by the previous r-ICustObjImp1 sample class. Here, it calculates the customer balance from the total of Invoice.Amount values in its related Invoice records and assigns the HighCustBalance and HighCustNum property values accordingly.

The following r-ICustObjProc2.p sample procedure shows an application of the r-ICustObjImp2 class, which is very similar to the previous procedure, r-ICustObjProc.p. The differences include displaying both the stored Customer.Balance value and the Invoice.Amount total for the selected Customer record, as well as some cosmetic changes to the display. Otherwise, the application is identical.
You can terminate an INTERFACE statement with either a period (.) or a colon (:) but typically use a colon (:).

A class definition (.cls) file can contain only one interface definition that is optionally preceded by one or more USING statements. The complete interface definition must begin with the INTERFACE statement and end with the END statement, and the INTERFACE statement must be the first compileable statement after any USING statements in the file. A class definition file containing an interface definition cannot also contain a class definition.

The access mode for an interface definition is always PUBLIC.
• The compiled version of an interface definition file is an r-code (.r) file. For more information, see the COMPILE statement reference entry.

• You can define an object reference variable for an interface, which lets you reference a class that implements the interface, but you cannot create an instance of an interface with the NEW function (classes). For more information on object references, see the AS CLASS option in the DEFINE VARIABLE statement reference entry and see the Class-based object reference reference entry.

• You can reference include files from within an interface definition. For more information about include files, see the { } Include file reference entry.

• All built-in preprocessor directives are supported in interface definitions.

• All built-in preprocessor names are supported in interface definitions. For a list of preprocessor name, see the { } Preprocessor name reference entry.

• You cannot pass compile-time arguments to interface definition files. However, you can pass compile-time arguments to include files referenced in an interface definition file.

• You can store class definition r-code files in ABL procedure libraries. If ABL encounters a procedure library on PROPATH, it will search the library for the specified r-code. However, you cannot execute r-code files stored in a procedure library that is not on PROPATH using the procedure-library-path<<member-name>> syntax.

• While a property interface declaration may include a GET and SET accessor, or a GET accessor, or a SET accessor, you cannot force the property to NOT have a particular accessor in an implementing class. However, you can force the accessor to be missing when an instance of the class is used through an interface reference. You can do this by omitting the accessor in the property interface definition. Even though the accessor might be implemented in the class property, it will appear, when used through an interface reference, that the accessor implementation does not exist.

See also Class-based object reference, CLASS statement, DEFINE DATASET statement, DEFINE EVENT statement, DEFINE PROPERTY statement, DEFINE TEMP-TABLE statement, METHOD statement, Type-name syntax, USING statement

INTERVAL function

Returns the time interval between two DATE, DATETIME, or DATETIME-TZ values as an INT64 value.

Syntax

```
INTERVAL (datetime1, datetime2, interval-unit)
```

`datetime1`

An expression whose value is a DATE, DATETIME, or DATETIME-TZ.

`datetime2`

An expression whose value is a DATE, DATETIME, or DATETIME-TZ.
interval-unit

A character constant, or a character expression that evaluates to one of the following time units: 'years', 'months', 'weeks', 'days', 'hours', 'minutes', 'seconds' or 'milliseconds'. These values are case insensitive and might be singular.

Notes
- This function returns a signed integer value (positive or negative). For example, if datetime1 is less than datetime2, the INTERVAL function returns a negative value.
- If datetime1 or datetime2 is a DATE or DATETIME, the time value defaults to midnight and the time zone value defaults to the session's time zone, respectively.
- You are responsible for managing value overflow, if any.

See also
- Date subtraction operator, – Datetime subtraction operator, ADD-INTERVAL function, DATE function, DATETIME function, DATETIME-TZ function

IS-ATTR-SPACE function

This function is supported only for backward compatibility.

Note: Does not apply to SpeedScript programming.

Syntax

```is-attr-space```

Example

This procedure displays a message indicating whether the current terminal is space-taking:

```isattr.p```

```define variable termtype as logical format "spacetaking/non-spacetaking".
termtype = is-attr-space.
display "You are currently using a" termtype no-label "terminal"
with frame d1 centered row 5.
```

Note
If you run ABL in batch mode, IS-ATTR-SPACE returns the Unknown value (?).

See also
TERMINAL statement

IS-CODEPAGE-FIXED function

Returns TRUE if the code page of the specified LONGCHAR variable is fixed; otherwise it returns FALSE.

Syntax

```
is-codepage-fixed ( longchar )
```
**IS-COLUMN-CODEPAGE function**

Returns TRUE if the specified CLOB field is a COLUMN-CODEPAGE CLOB. Otherwise, it returns FALSE (that is, if the CLOB is a DBCODEPAGE CLOB or a TTCODEPAGE CLOB).

**Syntax**

```
IS-COLUMN-CODEPAGE ( field )
```

**field**

The name of a CLOB field.

---

**IS-LEAD-BYTE function**

Returns TRUE if the first character of the string is the lead-byte of a multi-byte character. Returns FALSE if it is not.

**Syntax**

```
IS-LEAD-BYTE ( string )
```

**string**

A character expression (a constant, field name, variable name, or any combination of these) whose value is a character.

**Example**

In this example, IS-LEAD-BYTE returns TRUE because the first byte of the first character is the lead-byte of a double-byte character. The output is “Lead: yes”:

```
DEFINE VARIABLE Lead AS LOGICAL.
Lead = IS-LEAD-BYTE ("dı xy").
DISPLAY Lead WITH 1 COLUMN.
```

**See also**

OVERLAY statement, SUBSTRING statement

---

**ISO-DATE function**

Returns a character representation of a DATE, DATETIME, or DATETIME-TZ that conforms to the ISO 8601 standard for date/time representations.
Note: These formats are equivalent to the XML Schema date and dateTime formats.

Syntax

ISO-DATE ( expression )

expression

An expression that evaluates to a DATE, DATETIME or DATETIME-TZ.

The ISO-DATE function returns the character string in the standard ISO format of the data type. Table 43 lists the standard ISO formats for each data type.

Table 43: Standard ISO formats

<table>
<thead>
<tr>
<th>Data type</th>
<th>ISO format</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATE</td>
<td>YYYY-MM-DD</td>
</tr>
<tr>
<td>DATETIME</td>
<td>YYYY-MM-DDTHH:MM:SS.SSS</td>
</tr>
<tr>
<td>DATETIME-TZ</td>
<td>YYYY-MM-DDTHH:MM:SS.SSS+HH:MM</td>
</tr>
</tbody>
</table>

KBLABEL function

Returns the keyboard label (such as F1) of the key that performs a specified ABL function (such as GO).

Note: Does not apply to SpeedScript programming.

Syntax

KLABEL ( key-function )

key-function

An expression whose value is the name of the special ABL key function. See OpenEdge Development: Programming Interfaces for possible values of key-name. If key-function is a constant, enclose it in quotation marks (""). See the same chapter for a list of key functions and the corresponding standard keyboard keys.

Example

The r-kblab1.p procedure allows the user to update some of the fields in each of the customer records, and displays a message in the status message area at the bottom of the window:
KEYCODE function

Evaluates a key label (such as F1) for a key in the predefined set of keyboard keys and returns the corresponding = key code (such as 301) as an INTEGER value. See *OpenEdge Development: Programming Interfaces* for a list of key codes and key labels.

**Note:** Does not apply to SpeedScript programming.

### Syntax

```plaintext
KEYCODE ( key-label )
```

*key-label*

A constant, field name, variable name, or expression that evaluates to a character string that contains a key label. If `key-label` is a constant, enclose it in quotation marks (" ")

### Example

This procedure displays a menu and highlights different selections on the menu depending on which key you press. On the first iteration of the REPEAT block, the COLOR statement tells the AVM to color `msg[ix]` with the same color used to display messages. Because the initial value of `ix` is 1, `msg[ix]` is the first menu selection. Therefore, the first menu selection is colored MESSAGES.
r-keycod.p

```
DEFINE VARIABLE msg  AS CHARACTER NO-UNDO EXTENT 3.
DEFINE VARIABLE ix   AS INTEGER  NO-UNDO INITIAL 1.
DEFINE VARIABLE newi AS INTEGER  NO-UNDO INITIAL 1.

DISPLAY
"   Please choose   " SKIP(1)
" 1  Run order entry  " @ msg[1]
  ATTR-SPACE SKIP
" 2  Run receivables  " @ msg[2]
  ATTR-SPACE SKIP
" 3  Exit            " @ msg[3]
  ATTR-SPACE SKIP
WITH CENTERED FRAME menu NO-LABELS.

REPEAT:
  COLOR DISPLAY MESSAGES msg[ix] WITH FRAME menu.
  READKEY.
  IF LASTKEY = KEYCODE("CURSOR-DOWN") AND ix < 3 THEN
    newi = ix + 1.
  ELSE IF LASTKEY = KEYCODE("CURSOR-UP") AND ix > 1 THEN
    newi = ix - 1.
  ELSE IF LASTKEY = KEYCODE("GO") OR LASTKEY = KEYCODE("RETURN") THEN LEAVE.
  IF ix <> newi THEN
    COLOR DISPLAY NORMAL msg[ix] WITH FRAME menu.
    ix = newi.
END.
```

When you press the cursor-down key, the following occurs:

1. The READKEY statement reads the value of the key you pressed.
2. The first IF . . . THEN . . . ELSE statement tests to see if the key code of the key you pressed is CURSOR-DOWN. It also checks whether the value of ix is less than 3. Both of these things are true, so the procedure adds one to the value of newi, making newi equal two.
3. The next two IF statements are ignored because the condition in the first IF statement was true. The procedure continues on the last IF statement: IF ix <> newi THEN COLOR DISPLAY NORMAL msg[ix] WITH FRAME menu.
4. Remember, ix is still 1 but newi is now 2. Thus, ix is not equal to newi. Which means that the IF statement test is true. Therefore, the AVM colors msg[ix], which is still msg[1] (the first menu selection), NORMAL. So the first menu selection is no longer highlighted.
5. Just before the end of the REPEAT block, ix is set equal to newi. Which means that msg[ix] is now msg[2], or the second menu selection.
6. On the next iteration, the COLOR statement colors msg[ix], that is the second menu selection, MESSAGES. The end result of pressing CURSOR-DOWN is that the highlight bar moves to the second menu selection.

See also    KEYFUNCTION function, KEYLABEL function
KEYFUNCTION function

Evaluates an integer expression (such as 301) and returns a character string that is the function of the key associated with that integer expression (such as GO).

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
KEYFUNCTION ( expression )
```

*expression*

A constant, field name, variable name, or expression whose value is an integer key code.

**Example**

This procedure displays a menu and highlights different selections, depending on which key you press. On the first iteration of the REPEAT block, the COLOR statement tells the AVM to color msg[ix] with the same color used to display messages. Because the initial value of ix is 1, msg[ix] is the first menu selection. Therefore, the first menu selection is colored MESSAGES.

```
r-keyfn.p

DEFINE VARIABLE msg  AS CHARACTER NO-UNDO EXTENT 3.
DEFINE VARIABLE ix  AS INTEGER NO-UNDO INITIAL 1.
DEFINE VARIABLE newi AS INTEGER NO-UNDO INITIAL 1.
DEFINE VARIABLE func AS CHARACTER NO-UNDO.

DISPLAY
"     Please choose     " SKIP(1)
" 1  Run order entry    " @ msg[1] ATTR-SPACE SKIP
" 2  Run receivables   " @ msg[2] ATTR-SPACE SKIP
" 3  Exit               " @ msg[3] ATTR-SPACE SKIP
WITH CENTERED FRAME menu NO-LABELS.

REPEAT:
COLOR DISPLAY MESSAGES msg[ix] WITH FRAME menu.
READKEY.
func = KEYFUNCTION(LASTKEY).
IF func = "CURSOR-DOWN" AND ix < 3 THEN
   newi = ix + 1.
ELSE IF func = "CURSOR-UP" AND ix > 1 THEN
   newi = ix - 1.
ELSE IF func = "GO" OR func = "RETURN" THEN LEAVE.
IF ix <> newi THEN
   COLOR DISPLAY NORMAL msg[ix] WITH FRAME menu.
   ix = newi.
END.
```

See the example in the KEYCODE function reference entry for details on what happens if you press keylabel component.

**Notes**

- The value returned by the KEYFUNCTION function is affected by any ON statements you use to redefine the value of the key represented by *expression*.
- If the key represented by *expression* has no function currently assigned to it or if it has the function of BELL, KEYFUNCTION returns a null value.
• KEYFUNCTION(-2) is equal to ENDKEY.

See also KEYCODE function, KEYLABEL function

KEYLABEL function

Evaluates a key code (such as 301) and returns a character string that is the predefined keyboard label for that key (such as F1).

Note: Does not apply to SpeedScript programming.

Syntax

KEYLABEL ( key-code )

key-code

The key code of the key whose label you want to know. A special case of key-code is LASTKEY. See OpenEdge Development: Programming Interfaces for a list of key codes and key labels.

Example

This procedure reads each keystroke the user makes, leaving the procedure only when the user presses GO. The KEYLABEL function tests the LASTKEY pressed, and returns the label of the key. (Remember that the value in LASTKEY is the key code of the last key pressed.)

r-keybl.p

DISPLAY "Press the " + KBLABEL("GO") + " key to leave procedure"
FORMAT "x(50)".
REPEAT:
READKEY.
HIDE MESSAGE.
IF LASTKEY = KEYCODE(KBLABEL("GO")) THEN RETURN.
MESSAGE "Sorry, you pressed the" KEYLABEL(LASTKEY) "key.".
END.

Note

Some key codes can be associated with more than one key label. The KEYLABEL function always returns the label listed first in the ABL table of key labels.

See also KEYCODE function, KEYFUNCTION function

KEYWORD function

Returns a character value that indicates whether a string is an ABL reserved keyword.

Syntax

KEYWORD ( expression )
KEYWORD-ALL function

expression

A constant, field name, variable name, or expression that results in a character string. If expression matches an ABL reserved keyword or valid abbreviation of a reserved keyword, the KEYWORD function returns the full keyword. If there is no match, the KEYWORD function returns the Unknown value (?).

In some cases, the abbreviation for a keyword is also a keyword. For example, if expression is “def” (the abbreviation for DEFINE) or “col” (the abbreviation for COLUMN), the KEYWORD function returns the values “def” and “col”, respectively.

If you use the Run-time client, the KEYWORD function always returns the Unknown value (?).

Example

In this example, the KEYWORD function tests the value of formname. If the user tries to use a reserved word as a form name, the AVM displays a message to try again.

r-keywd.p

```asm
DEFINE VARIABLE formname AS CHARACTER NO-UNDO FORMAT "x(20)".
REPEAT ON ERROR UNDO, RETRY:
  UPDATE formname.
  IF KEYWORD(formname) NE ? THEN DO:
    MESSAGE formname + " may not be used as a form name".
    UNDO, RETRY.
  END.
  ELSE LEAVE.
END.
```

Notes

• Because KEYWORD recognizes abbreviations, it does not distinguish between FORM and FORMAT or between ACCUM and ACCUMULATE.

• This function returns the Unknown value (?) for colors and most data types, as well as all unreserved keywords. See the “Keyword Index” section on page 1971 for a list of ABL reserved and unreserved keywords.

• KEYWORD is less restrictive than the KEYWORD-ALL function. Use this function if you do not want to use ABL reserved keywords as field names, for example.

• For SpeedScript, all ABL reserved keywords are also reserved for SpeedScript.

See also

KEYWORD-ALL function

KEYWORD-ALL function

Returns a character value that indicates whether a string is an ABL keyword. This function returns all keywords and does not distinguish between reserved or unreserved keywords.

Syntax

```asc
KEYWORD-ALL ( expression )
```
**KEYWORD-ALL function**

**expression**

A constant, field name, variable name, or expression that results in a character string. If expression matches an ABL keyword, whether reserved or unreserved or valid abbreviation of a keyword, the KEYWORD-ALL function returns the full keyword. If there is no match, the KEYWORD-ALL function returns the Unknown value (?)

KEYWORD-ALL is the same function as KEYWORD in Progress Version 6 and earlier. Use this function if you do not want to use ABL reserved and unreserved keywords as field names, for example.

In some cases, the abbreviation for a keyword is also a keyword. For example, if expression is “def” (the abbreviation for DEFINE) or “col” (the abbreviation for COLUMN), the KEYWORD function returns the values “def” and “col”, respectively.

If you use the Run-time client, the KEYWORD-ALL function always returns the Unknown value (?).

**Example**

In this example, the KEYWORD-ALL function tests the value of formname. If the user tries to use a keyword as a form name, the AVM displays a message to try again.

### r-keywda.p

```plaintext
DEFINE VARIABLE formname AS CHARACTER NO-UNDO FORMAT "x(20)".

REPEAT ON ERROR UNDO, RETRY:
  UPDATE formname.
  IF KEYWORD-ALL(formname) NE ? THEN DO:
    MESSAGE formname + "cannot be used as a form name".
    UNDO, RETRY.
  END.
  ELSE LEAVE.
END.
```

**Notes**

- Because KEYWORD-ALL recognizes abbreviations, it does not distinguish between FORM and FORMAT or between ACCUM and ACCUMULATE.

- This function returns the Unknown value (?) for colors and most data types, as well as all unreserved keywords. See the “Keyword Index” section on page 1971 for a list of ABL reserved and unreserved keywords.

- For SpeedScript, all ABL reserved keywords are also reserved for SpeedScript.

**See also**

KEYWORD function
LAST function

Returns a TRUE value if the current iteration of a DO, FOR EACH, or REPEAT...BREAK block is the last iteration of that block.

Syntax

```
LAST ( break-group )
```

**break-group**

The name of a field or expression you named in the block header with the BREAK BY option.

Example

The first FOR EACH block produces a list of the on hand values of the items in inventory. It also automatically generates a total of these on hand values.

The second FOR EACH block does exactly the same thing, except it does not generate the total. Instead, the procedure uses the ACCUMULATE statement and the LAST function. Thus, you can substitute your own labels and formats for the grand total.

```
r-last.p
```

```
FOR EACH Item NO-LOCK BY Item.OnHand * Item.Price DESCENDING:
    DISPLAY Item.ItemNum Item.OnHand * Item.Price (TOTAL) LABEL "Value-oh"
    WITH USE-TEXT.
END.

FOR EACH Item NO-LOCK BREAK BY Item.OnHand * Item.Price DESCENDING:
    FORM Item.ItemNum value-oh AS DECIMAL LABEL "Value-oh"
    WITH COLUMN 40 USE-TEXT.
    DISPLAY Item.ItemNum Item.OnHand * Item.Price @ value-oh.
    IF LAST(Item.OnHand * Item.Price) THEN DO:
        UNDERLINE value-oh.
        DISPLAY ACCUM TOTAL Item.OnHand * Item.Price @ value-oh.
    END.
END.
```

See also

FIRST function, FIRST-OF function, LAST-OF function

LASTKEY function

Returns, as an INTEGER value, the integer key code of the most recent event read from the user (that is, from the keyboard or mouse) during an interaction with a procedure.

**Note:** Does not apply to SpeedScript programming.

Syntax

```
LASTKEY
```
In this procedure, the user can move through the Customer file and update certain fields in each of the Customer records. The GO-ON option tells the procedure to continue on to the following statements if the user presses F9, F10, or F12. To determine what action to take, the LASTKEY function compares the key code of the last key pressed with the key codes F9, F10, and F12.

```
DISPLAY "You may update each customer. After making your changes," SKIP
"Press one of:" SKIP(1)
KBLABEL(“GO”) "Make the changes permanent" SKIP
KBLABEL("END-ERROR") "Undo changes and exit" SKIP
"F9" SPACE(7) "Undo changes and try again" SKIP
"F10" SPACE(6) "Find next customer" SKIP
"F12" SPACE(6) "Find previous customer"
WITH CENTERED FRAME instr.
FIND FIRST Customer.
REPEAT:
  Customer.State GO-ON(F9 F10 F12) WITH 1 DOWN.
  IF LASTKEY = KEYCODE("F9") THEN UNDO, RETRY.
  ELSE IF LASTKEY = KEYCODE("F10") THEN FIND NEXT Customer.
  ELSE IF LASTKEY = KEYCODE("F12") THEN FIND PREV Customer.
END.
```

Notes

- The LASTKEY function is double-byte enabled. The LASTKEY function returns values only after the input method places the data in the keyboard buffer. It returns the key code of the most recent key sequence returned from the keyboard buffer. A key sequence is the set of keystrokes necessary to generate one character or function key event in ABL.

- If you used a READKEY statement that timed out (you specified a number of seconds by using the PAUSE option with the READKEY statement), or if a PAUSE statement times out, the value of LASTKEY is -1.

- If you use the PAUSE option with the READKEY statement, the value of LASTKEY is the key you press to end the PAUSE.

- When the ABL session starts, the value of LASTKEY is -1. This value remains the same until the first input, READKEY, or procedure pause occurs. The LASTKEY function is reset to -1 each time you return to the Procedure Editor.

- If you read data from a file, LASTKEY is set to the last character read from the file. For an INSERT, PROMPT-FOR, SET or UPDATE statement, this is always KEYCODE("RETURN"). For a READKEY statement, this is the character read from the file. If you reach past the end of the file, LASTKEY is -2.

- For more information on keys, see OpenEdge Development: Programming Interfaces.

See also

READKEY statement

LAST-OF function

Returns a TRUE value if the current iteration of a DO, FOR EACH, or REPEAT . . . BREAK block is the last iteration for a particular value of a break group.
**LC function**

**Syntax**

| LAST-OF ( break-group ) |

*break-group*

The name of a field or expression you named in the block header with the BREAK BY option.

**Example**

This procedure uses LAST-OF to display a single line of information on each Item.CatPage group in the Item file, without displaying any individual item data. It produces a report that shows the aggregate value OnHand for each catalog page.

```plaintext
r-lastof.p

FOR EACH Item NO-LOCK BREAK BY Item.CatPage:
    IF LAST-OF(Item.CatPage) THEN
        DISPLAY Item.CatPage (ACCUM TOTAL BY Item.CatPage
            Item.OnHand * Item.Price) LABEL "Value-oh".
    END.
```

**See also** FIRST function, FIRST-OF function, LAST function

---

**LC function**

Converts any uppercase characters in a CHARACTER or LONGCHAR expression to lowercase characters, and returns the result.

**Syntax**

| LC ( expression ) |

*expression*

A constant, field name, variable name, or expression that results in a CHARACTER or LONGCHAR value.

**Example**

This procedure finds a Customer record. After the user updates the SalesRep field, the procedure converts the first character of the SalesRep value to uppercase and the remaining characters to lowercase.

```plaintext
r-lc.p

REPEAT:
    PROMPT-FOR Customer.CustNum.
    FIND Customer USING Customer.CustNum.
    DISPLAY Customer.Name.
    Customer.SalesRep = CAPS(SUBSTRING(Customer.SalesRep, 1, 1) ) +
        LC(SUBSTRING(Customer.SalesRep, 2) ).
END.
```

The CAPS function uses the SUBSTRING function to extract the first character of the field, which it then converts to uppercase.
In the LC function, the result of the SUBSTRING function is the remaining characters in the SalesRep field, starting with character position 2. (No length is specified, so the remainder of the string is assumed). The LC function converts these characters to lowercase.

**Notes**

- The LC function returns lowercase characters relative to the settings of the Internal Code Page (-cpinternal) and Case Table (-cpcase) startup parameters. For more information on these parameters, see *OpenEdge Deployment: Startup Command and Parameter Reference*.

- The LC function is double-byte enabled. The specified expression can yield a string containing double-byte characters; however, the LC function changes only single-byte characters in the string.

**See also**

CAPS function

### LDBNAME function

Returns the logical name of a database that is currently connected.

**Syntax**

```
LDBNAME
(  
  {  
    integer-expression
    | logical-name
    | alias
    | BUFFER bufname
  }
)
```

**integer-expression**

The sequence number of a database the ABL session is connected to. For example, LDBNAME(1) returns information on the first database the ABL session is connected to, LDBNAME(2) returns information on the second database the ABL session is connected to, etc. If you specify a sequence number that does not correspond to a database the ABL session is connected to, the LDBNAME function returns the Unknown value (?).

**logical-name or alias**

These forms of the LDBNAME function require a quoted character string or a character expression as a parameter. If the parameter is the logical name of a connected database or an alias of a connected database then the logical name is returned. Otherwise, the AVM returns the Unknown value (?).

**BUFFER bufname**

The name of a database table or buffer. The BUFFER option lets you determine the database a certain table belongs to without hard-coding the logical database name or alias.

**Example**

This procedure disconnects all currently connected databases. After a database is disconnected, the connected databases are renumbered to reflect the change. For example, if databases 1, 2, 3, and 4, are connected and the procedure disconnects database 3, database 4 becomes database 3.
Note

To determine if a particular name is an ALIAS or a logical database name, use the following procedure:

**r-tstnm.p**

```plaintext
DEFINE VARIABLE testnm AS CHARACTER NO-UNDO.

SET testnm.
IF LDBNAME(testnm) = testnm THEN
   MESSAGE testnm "is a true logical database name."
ELSE IF LDBNAME(testnm) = ? THEN
   MESSAGE testnm "is not the name or alias of any connected database."
ELSE
   MESSAGE testnm "is an ALIAS for database " LDBNAME(testnm).
```

---

**LE or <= operator**

Returns a TRUE value if the first of two expressions is less than or equal to the second.

**Syntax**

```plaintext
expression { LE | <= } expression
```

**expression**

A constant, field name, variable name, or expression. The expressions on either side of the LE or <= must be of the same data type, although one can be integer and the other decimal.

**Example**

This procedure lists all the items with zero or negative on-hand quantities:

**r-le.p**

```plaintext
FOR EACH Item WHERE Item.OnHand <= 0:
END.
```

**Notes**

- By default, the AVM uses the collation rules you specify to compare characters and sort records. The collation rules specified with the Collation Table (-cpcoll) startup parameter take precedence over a collation specified for any database the AVM accesses during the session, except when the AVM uses or modifies pre-existing indexes. If you do not specify a collation with the -cpcoll startup parameter, the AVM uses the language collation rules defined for the first database on the command line. If you do not specify a database on the
command line, the AVM uses the collation rules with the default name "basic" (which might or might not exist in the convmap.cp file).

- If either of the expressions is the Unknown value (?), then the result is the Unknown value (?); if both of the expressions are the Unknown value (?), then the result is TRUE.

- You can compare character strings with LE. Most character comparisons are case insensitive in ABL. That is, upper-case and lower-case characters have the same sort value. However, it is possible to define fields and variables as case sensitive (although it is not advised, unless strict ANSI SQL adherence is required). If either expression is a field or variable defined as case sensitive, the comparison is case sensitive and “Smith” does not equal “smith”.

- Characters are converted to their sort code values for comparison. Using the default case-sensitive collation table, all uppercase letters sort before all lowercase letters (for example, a is greater than Z, but less than b.) Note also that in character code uppercase A is less than [ . \ , ^ , _, and ’, but lowercase a is greater than these.

- You cannot compare data of different DATE, DATETIME, and DATETIME-TZ data types to each other using LE. You must first convert different date and datetime data types to the same data type before doing a comparison between them.

- You can use LE to compare a LONGCHAR variable to another LONGCHAR or CHARACTER variable. The variable values are converted to -cpinternal for comparison and must convert without error, or the AVM raises a run-time error.

- You cannot use LE to compare one CLOB field to another.

---

**LEAVE statement**

Exits from a block. Execution continues with the first statement after the end of the block.

**Syntax**

```
LEAVE [ label ]
```

`label`

The name of the block you want to leave. If you do not name a block, the AVM leaves the innermost iterating block that contains the LEAVE statement. If there is no such block, then the AVM leaves the procedure block.

**Example**

This procedure represents part of a menu program. If the user chooses N, P, F, or Q, the procedure leaves the inner choose block and goes on to process the menu selection. If the user presses any other key, the procedure rings the terminal bell.
LEFT-TRIM function

Removes leading white space, or other specified characters, from a CHARACTER or LONGCHAR expression.

Syntax

```
LEFT-TRIM ( expression [, trim-chars ] )
```

**expression**

An expression (a constant, field name, variable name, or expression) whose value is a CHARACTER or LONGCHAR. If `expression` is a case-sensitive variable, the AVM performs a case-sensitive trim. If `expression` is a LONGCHAR, the result is in the same code page.

**trim-chars**

A character expression that specifies the characters to be trimmed from `expression`. If you do not specify `trim-chars`, the LEFT-TRIM function removes spaces, tabs, line feeds, and carriage returns.

**Example**

The following example shows the effect of the TRIM, LEFT-TRIM, and RIGHT-TRIM functions on a string value:

```r-leave.p
DEFINE VARIABLE valid-choice AS CHARACTER NO-UNDO INITIAL "NPFQ".
DEFINE VARIABLE selection AS CHARACTER NO-UNDO FORMAT "x".

main-loop:
    REPEAT:
        choose:
            REPEAT ON ENDKEY UNDO choose, RETURN:
                UPDATE selection AUTO-RETURN.
                /* Selection was valid */
                IF INDEX(valid-choice, selection) <> 0 THEN LEAVE choose.
                BELL.
            END. /* choose */
        /* Processing for menu choices N, P, F here */
        IF selection = "Q" THEN LEAVE main-loop.
    END. /* REPEAT */
```

See also

NEXT statement, RETURN statement, UNDO statement
Notes

- The LEFT-TRIM function is similar to the TRIM function except that it trims characters only from the left end of the string.

- If expression is a case-sensitive field or variable, then trim-chars is also as case sensitive. Otherwise, trim-chars is not case sensitive.

- The LEFT-TRIM function is double-byte enabled. The specified expression and trim-chars arguments can contain double-byte characters. LEFT-TRIM does not remove double-byte space characters by default.

See also

RIGHT-TRIM function, TRIM function

LENGTH function

Returns, as an INTEGER value, the number of characters, bytes, or columns in a string, an expression of type RAW, or a BLOB field.

Syntax

```
LENGTH ( { string | raw-expression | blob-field } [ , type ] )
```
**string**

A character expression. The specified *string* can be a character string, a CLOB field, or a LONGCHAR variable, and may contain double-byte characters.

**raw-expression**

A function or variable name that returns a RAW value.

**blob-field**

An expression that evaluates to a BLOB field.

**type**

A character expression that indicates whether you want the length of *string* in character units, bytes, or columns. A double-byte character registers as one character unit. By default, the unit of measurement is character units.

There are three valid types: "CHARACTER," "RAW," and "COLUMN." The expression "CHARACTER" indicates that the length is measured in characters, including double-byte characters. The expression "RAW" indicates that the length is measured in bytes. The expression "COLUMN" indicates that the length is measured in display or print character-columns. If you specify the *type* as a constant expression, ABL validates the type specification at compile time. If you specify the *type* as a non-constant expression, the AVM validates the type specification at run time.

**Note:** The expression "COLUMN" is not valid for a LONGCHAR variable or a CLOB field.

### Examples

This procedure produces a report that contains item information. Because the information on the report fills the entire width of the screen, this procedure shortens the information in the description field for each item. If the description of an item is longer than eight characters, the procedure converts the description to the first eight characters followed by ellipses.

```plaintext
DEFINe VARIABLE short-name AS CHARACTER NO-UNDO FORMAT "x(11)" LABEL "Desc".

FOR EACH Item NO-LOCK:
    IF LENGTH(Item.ItemName, "CHARACTER") > 8 THEN
        short-name = SUBSTRING(Item.ItemName,1,8, "FIXED") + "...".
    ELSE
        short-name = Item.ItemName.
    END.
END.
```

In this procedure, the LENGTH function returns the number of bytes in the Name of number 29. The procedure returns a 15, the number of bytes in the Name, Bug in a Rug-by.
LENGTH statement

Changes the number of bytes in a raw variable.

Syntax

```
LENGTH ( variable ) = expression
```

- **variable**
  - A variable of type RAW.
- **expression**
  - An expression that returns an integer.

Example

This procedure takes the number of bytes in the name stored in the variable r1 and truncates it to 2 bytes:

```
r-rawln1.p
/* You must connect to a non-OpenEdge demo database to run this procedure */
DEFINE VARIABLE r1 as RAW NO-UNDO.
FIND Customer NO-LOCK WHERE Customer.CustNum = 29.
r1 = RAW(Customer.Name).
LENGTH(r1) = 2.
```

Notes

- If **variable** is the Unknown value (?), it remains the Unknown value (?).
- If **expression** is greater than the number of bytes in **variable**, the AVM appends null bytes so that the length of **variable** equals the length of **expression**.

LIBRARY function

Parses a character string in the form `path-name<<member-name>>`, where **path-name** is the pathname of an ABL r-code library and **member-name** is the name of a file within the library, and returns the pathname of the library. The double angle brackets indicate that **member-name** is a file in a library. If the string is not in this form, the LIBRARY function returns the Unknown value (?).
LINE-COUNTER function

Typically, you use the LIBRARY function with the SEARCH function to retrieve the name of a library. The SEARCH function returns character strings of the form path-name<<member-name>> if it finds a file in a library.

Syntax

LIBRARY ( string )

string

A character expression whose value is the pathname of a file in a library.

Example

This procedure searches for a file that you specify. It displays a message indicating whether the file is not found in your path, is found in a library within your path, or is found in your path but not in a library.

r-rlib.p

```
DEFINE VARIABLE what-lib AS CHARACTER NO-UNDO.
DEFINE VARIABLE location AS CHARACTER NO-UNDO.
DEFINE VARIABLE myfile   AS CHARACTER NO-UNDO FORMAT "x(16)"
   LABEL "R-code File".

SET myfile.
 location = SEARCH(myfile).
 IF location = ?THEN DO:
   MESSAGE "Can't find" myfile.
   LEAVE.
 END.

what-lib = LIBRARY(location).
 IF what-lib <> ? THEN
   MESSAGE myfile "can be found in library" what-lib.
 ELSE
   MESSAGE myfile "is not in a library but is in" location.
```

Note

You can improve the performance of an application by using the SEARCH and LIBRARY functions for any files you want to execute that you specify with a relative pathname. For example, if you want to execute a procedure file several times that you specify with a relative pathname, you can return the absolute pathname for the file using the SEARCH and LIBRARY functions, then execute the RUN statement with that absolute pathname, which avoids any need for the RUN statement to search PROPATH each time.

See also MEMBER function, SEARCH function

LINE-COUNTER function

Returns the current line number of paged output as an INTEGER value.

The initial value of LINE-COUNTER is 1. At the completion of each DISPLAY statement, the AVM increments LINE-COUNTER by the number of lines that were output in that DISPLAY statement. LINE-COUNTER continues to increase until after at least one line has been printed on a new page.

LINE-COUNTER returns a 0 if the output is not paged.
Syntax

LINE-COUNTER [ ( stream | STREAM-HANDLE handle ) ]

stream

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream. For more information on streams, see this book’s DEFINE STREAM statement reference entry and OpenEdge Development: Programming Interfaces.

STREAM-HANDLE handle

Specifies the handle to a stream. If handle it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams and stream handles.

Example

This procedure prints a Customer report, categorized by State. At the end of each State category, it tests to see if there are at least four lines left on the page. The LINE-COUNTER function returns the current line number of output. If that number plus four is greater than the total number of lines on the page (returned by the PAGE-SIZE function), then the procedure starts the new page. If there are four or more lines left, the procedure skips a line before printing the next customer record.

r-linec.p

OUTPUT TO PRINTER.
FOR EACH Customer BREAK BY Customer.State:
    IF LAST-OF(Customer.State) THEN DO:
        IF LINE-COUNTER + 4 > PAGE-SIZE THEN PAGE.
        ELSE DOWN 1.
    END.
END.
END.

Notes

• When output is sent to a device other than the terminal screen, the AVM defers displaying a frame until another frame is displayed. That way, if you display the same frame several times consecutively, the AVM performs all those displays at once. Because of this optimization, if the last display fills the page, the value returned by the LINE-COUNTER function can be larger than the page size, even though the next frame is displayed at the start of the new page.

• Use a procedure like this one to verify that output is positioned on the first non-header line of a new page:
LIST-EVENTS function

LIST-EVENTS function

Returns a comma-separated list of the valid events for a specified object or widget.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
LIST-EVENTS ( handle [, platform ] )
```

**handle**

A handle to a valid object or widget. The function returns a list of the events that are valid for that object or widget.

**platform**

A character-string value that specifies a display type. Valid values are GUI and TTY. Some events are valid only on certain platforms. If you omit the `platform` parameter, the AVM uses the platform for the current session.

**Example**

The following example uses the LIST-EVENTS function to populate a selection list with all the valid events for a widget. When you run this procedure, type `?` at any time to see a list of valid events for the widget that currently has focus.

```
LIST-QUERY-ATTRS function

Returns a comma-separated list of attributes and methods that are supported for an object or widget.

Syntax

```
LIST-QUERY-ATTRS ( handle )
```

**handle**

A handle to a valid object or widget. The function returns a list of the attributes and methods that are supported for that object or widget.

Example

The following example uses the LIST-QUERY-ATTRS and LIST-SET-ATTRS functions to populate selection lists with the valid attributes and methods for a specified widget. When you run this procedure, type `?` at any time to see lists of valid attributes for the widget that currently has focus.

---

r-levent.p

```
DEFINE VARIABLE inv-price NO-UNDO LIKE item.price.
DEFINE VARIABLE inv-value NO-UNDO LIKE item.price.
DEFINE VARIABLE report-type AS INTEGER NO-UNDO INITIAL 1.

DEFINE VARIABLE event-list AS CHARACTER NO-UNDO VIEW-AS SELECTION-LIST INNER-CHARS 20 INNER-LINES 5 SCROLLBAR-VERTICAL.

DEFINE BUTTON ok-butt LABEL "OK" AUTO-GO.
DEFINE BUTTON cancel-butt LABEL "CANCEL" AUTO-ENDKEY.

FORM
  inv-price LABEL "Price" AT ROW 1.25 COLUMN 2
  report-type LABEL "Report Sorted ..." AT ROW 2.25 COLUMN 2 VIEW-AS RADIO-SET RADIO-BUTTONS "By Catalog Page", 1, "By Inventory Value", 2 SKIP
  ok-butt cancel-butt
  WITH FRAME select-frame SIDE-LABELS.

FORM event-list
  WITH FRAME list-frame NO-LABELS TITLE "Events" WIDTH 30.

ON ? ANYWHERE DO:
  FRAME list-frame:TITLE = "Events for " + FOCUS:TYPE.
  event-list:LIST-ITEMS IN FRAME list-frame = LIST-EVENTS(FOCUS).
  DISPLAY event-list WITH FRAME list-frame.
  ENABLE event-list WITH FRAME list-frame.
  RETURN NO-APPLY.

See also

LAST-EVENT system handle, LIST-QUERY-ATTRS function, LIST-SET-ATTRS function, LIST-WIDGETS function, VALID-EVENT function
LIST-SET-ATTRS function

Returns a comma-separated list of attributes that can be set for an object or widget.

Syntax

```
LIST-SET-ATTRS ( handle )
```

**handle**

A handle to a valid object or widget. The function returns a list of the attributes that can be set for that object or widget.

Example

For an example of the LIST-SET-ATTRS function, see the LIST-QUERY-ATTRS function reference entry.

See also

CAN-QUERY function, CAN-SET function, LAST-EVENT system handle, LIST-EVENTS function, LIST-SET-ATTRS function, LIST-WIDGETS function, VALID-EVENT function
LIST-WIDGETS function

Returns a comma-separated list of objects and widget types that respond to a specified event.

Note: Does not apply to SpeedScript programming.

Syntax

```
LIST-WIDGETS ( event-name [ , platform ] )
```

event-name

A character-string expression that evaluates to an event name.

platform

A character-string value that specifies a display type. Valid values are GUI and TTY. Some events are valid only on certain platforms. If you omit the platform parameter, the AVM uses the platform for the current session.

Example

The following example prompts for an event name and then displays a list of widget types that support that event:

```
r-lwids.p
```

```
DEFINE VARIABLE event-name AS CHARACTER NO-UNDO FORMAT "x(24)"
LABEL "Event".
DEFINE VARIABLE widget-list AS CHARACTER NO-UNDO LABEL "Widgets"
    VIEW-AS SELECTION-LIST INNER-CHARS 24 INNER-LINES 6 SCROLLBAR-VERTICAL.
FORM event-name SKIP widget-list
    WITH FRAME main-frame SIDE-LABELS.
REPEAT WITH FRAME main-frame:
    DISABLE widget-list.
    SET event-name.
    widget-list:LIST-ITEMS = LIST-WIDGETS(event-name).
    DISPLAY widget-list.
    ENABLE widget-list.
    PAUSE.
END.
```

See also

LAST-EVENT system handle, LIST-EVENTS function, LIST-QUERY-ATTRS function, LIST-SET-ATTRS function, VALID-EVENT function
LOAD statement (Windows only)

Creates application defaults, involving colors, fonts, environment variables, etc., or loads existing defaults, to a graphical or character application.

Specifically, the LOAD statement:

- Creates registry keys and initialization file entries
- Creates new initialization files
- Loads entries from the registry or from an existing initialization file

For more information on application defaults, see the chapter on colors and fonts in *OpenEdge Development: Programming Interfaces*.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
LOAD environment
  [ DIR directory ]
  [ APPLICATION ]
  [ NEW ]
  [ BASE-KEY { key-name | "INI" } ]
  [ NO-ERROR ]
```

**environment**

A CHARACTER expression that evaluates to one of the following:

- The name of a registry key to create
- The name of an initialization file to create
- The name of an existing registry key
- The name of an existing initialization file

**DIR directory**

A CHARACTER expression that evaluates to the directory path of one of the following:

- An existing initialization file
- An initialization file to create

If you omit this option, LOAD looks for an existing initialization file, or creates a new initialization file, in the working directory.

**APPLICATION**

Has no effect; supported only for backward compatibility.
NEW

Creates a new registry key or a new initialization file. If the key or file already exists, LOAD overwrites its data.

BASE-KEY  key-name  "INI"

Bypasses the standard search rules.

If you specify BASE-KEY  key-name, LOAD looks for or creates the environment in the registry only under base key  key-name.

If you specify BASE-KEY "INI" (the quotes are required), LOAD looks for or creates only the initialization file  environment.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE(  message-num  ) to retrieve a particular message, where  message-num  is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the
error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Example**

See the **USE statement** reference entry for an example.

**Notes**

- If you specify **LOAD environment**, **LOAD** searches for a registry key and for an existing initialization file, and tries to load one or the other. The search logic, which assumes that **environment** has the format `path\rootname.extension` (where `path` and `extension` are optional) and that `version` is the current OpenEdge version, is as follows:

  - Search the registry under HKEY_CURRENT_USER for `path\rootname.extension`. If found, load it.

  - Else search the registry under HKEY_CURRENT_USER for `SOFTWARE\PSC\PROGRESS\version\path\rootname.extension`. If found, load it.

  - Else search the registry under HKEY_CURRENT_USER for `SOFTWARE\path\rootname.extension`. If found, load it.

  - Else search the registry under HKEY_CURRENT_USER for `rootname`. If found, load it.

  - Else search the registry under HKEY_CURRENT_USER for `SOFTWARE\PSC\PROGRESS\version\rootname`. If found, load it.

  - Else search the registry under HKEY_LOCAL_MACHINE for `path\rootname.extension`. If found, load it.

  - Else search the registry under HKEY_LOCAL_MACHINE for `SOFTWARE\PSC\PROGRESS\version\path\rootname.extension`. If found, load it.

  - Else search the registry under HKEY_LOCAL_MACHINE for `SOFTWARE\path\rootname.extension`. If found, load it.
– Else search the registry under HKEY_LOCAL_MACHINE for rootname. If found, load it.

– Else search the registry under HKEY_LOCAL_MACHINE for SOFTWARE\PSC\PROGRESS\version\rootname. If found, load it.

– Else search the registry under HKEY_LOCAL_MACHINE for SOFTWARE\rootname. If found, load it.

– Else search for the initialization file path\rootname.extension. If found, load it.

– Else, error.

• If you specify LOAD environment BASE-KEY key-name, where key-name is the name of a registry base key, LOAD loads the registry key key-name\environment.

Registry base keys are as follows:

– HKEY_CLASSES_ROOT
– HKEY_CURRENT_CONFIG (Win95 and NT 4.0)
– HKEY_CURRENT_USER
– HKEY_DYN_DATA (Win95 and NT 4.0)
– HKEY_LOCAL_MACHINE
– HKEY_USERS

• If you specify LOAD environment BASE-KEY “INI,” LOAD loads the initialization file environment.

• If you specify LOAD environment NEW, LOAD creates a new key in the registry under HKEY_CURRENT_USER and names the new key environment.

• If you specify LOAD environment NEW BASE-KEY key-name, LOAD creates a new key in the registry under key-name and names the new key environment.

• If you specify LOAD environment NEW BASE-KEY “INI,” LOAD creates a new initialization file and names it environment.ini.

• To change the application environment, load defaults using the LOAD statement, make them current using the USE statement, then access them using the GET-KEY-VALUE and PUT-KEY-VALUE statements.

See also
GET-KEY-VALUE statement, LOAD statement, PUT-KEY-VALUE statement, UNLOAD statement, USE statement
LOAD-PICTURE statement
(Windows only; Graphical interfaces only)

Returns a COM-HANDLE to an OlePictureObject. You can use this COM-HANDLE to set graphical properties of controls.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
LOAD-PICTURE [ image ]
```

**image**

A CHARACTER expression representing the name of the graphical file. This file can have one of the following extensions: .BMP, .WMF, .EMF, .ICO, .CUR, .DIB. If the filename is not fully qualified, LOAD-PICTURE searches for a matching file on the user’s path.

**Example**

The following program fragment illustrates the use of the LOAD-PICTURE statement:

```
DEFINE VARIABLE chPic AS COM-HANDLE NO-UNDO.
DEFINE VARIABLE chControl AS COM-HANDLE NO-UNDO.

/* Get the COM-HANDLE of an Image control */

/* Use LOAD-PICTURE to get a COM-HANDLE to the bitmap contained in myPic.bmp */
chPic = LOAD-PICTURE("myPic.bmp").

/* Set the control's Picture property for the bitmap */
chControl:Picture = chPic.
```

**LOCKED function**

Returns a TRUE value if a record is not available to a prior FIND . . . NO-WAIT statement because another user has locked a record.

**Syntax**

```
LOCKED record
```

**record**

The name of a record or buffer.

To use the LOCKED function with a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

**Example**

The FIND statement in this procedure tries to retrieve a customer record according to a supplied customer number. Because of the NO-ERROR option, the FIND statement does not return an error if it cannot find the record. The NO-WAIT option causes FIND to return immediately if the record is in use by another user.
A record might not be available if it is locked (being used by another user) or does not exist. The LOCKED function returns a TRUE value if the record is locked. In this case, the r-locked.p procedure displays a message that the record is locked. If the record is not locked, the procedure displays a message that the record does not exist.

**Note:** The result of the LOCKED function depends on the lock mode specified. For example, if the FIND statement uses SHARE-LOCK and no user has an EXCLUSIVE-LOCK on the record, the LOCKED function returns FALSE. If the FIND statement uses SHARE-LOCK and another user has an EXCLUSIVE-LOCK on the record, the LOCKED function returns TRUE. The current copy of the record in the buffer to which the LOCKED function applies is not locked. Rather, LOCKED refers to an error condition that can occur if the record is locked. Consider using the NO-WAIT and NO-ERROR options on the FIND statement to return immediately and raise an error condition.

**See also** AMBIGUOUS function, AVAILABLE function, FIND statement, NEW function (record buffers)

**LOG function**

Calculates the logarithm of an expression using a specified base and returns that logarithm as a DECIMAL value.

**Syntax**

\[ \text{LOG ( expression [ , base ] )} \]

**expression**

A decimal expression that you want the logarithm of.

**base**

A numeric expression that is the base you want to use. If you do not specify a base, LOG returns the natural logarithm, base (e). The base must be greater than 1.

**Example**

This procedure prompts the user for a base and a number, and then displays the log of the number. The VALIDATE option on the UPDATE statement ensures that the user enters a base value greater than 1 and a number greater than 0.
LOGICAL function

Converts any data type into the LOGICAL data type.

Syntax

```
LOGICAL ( expression [, char-expression-format ] )
```

**expression**

An expression in the data type that you want to convert to logical.

**char-expression-format**

A character expression that evaluates to a valid logical format, such as "si/no", or "da/nyet". This argument is ignored unless expression is of CHARACTER type. Also, this argument is only needed if expression evaluates to something other than the usual TRUE or FALSE, or YES or NO values.

Example

The following code fragment illustrates the Logical function:

```
DEFINE VARIABLE mychar AS CHARACTER NO-UNDO.
DEFINE VARIABLE v-log AS LOGICAL NO-UNDO.

mychar = "si".

v-log = LOGICAL(mychar, "si/no")
/* v-log is TRUE */
```

Notes

- The LOG function is accurate to approximately 10 decimal places.
- After converting the base and exponent to floating-point format, the LOG function uses standard system routines. On some machines, the logarithm routines do not handle large numbers well and might cause your terminal to hang.

```
r-log.p
```

```
DEFINE VARIABLE base AS DECIMAL NO-UNDO FORMAT ">>>,.9999".
DEFINE VARIABLE number AS DECIMAL NO-UNDO.

REPEAT:
  UPDATE base VALIDATE(base > 1, "Base must be greater than 1").
  REPEAT:
    UPDATE number VALIDATE(number > 0, "Number must be positive").
    DISPLAY number LOG(number, base) LABEL "LOG(NUMBER, BASE)".
  END.
END.
```
logical values

If the value of expression is 0, it returns FALSE. The second argument is ignored if present.

- If expression is of type LONGCHAR or CHARACTER, it returns TRUE or FALSE depending on the value in the expression and the format used. Whether or not char-expression-format is given, the case-insensitive values TRUE, FALSE, YES, NO, abbreviated to 1 character, are always accepted. For example, a "Y" is interpreted as TRUE.

- If char-expression-format is given, it is validated. If it is not valid, an error message appears and the Unknown value (?) is returned. Otherwise, the format is used to interpret the character string if it is not one of the following: TRUE, FALSE, YES, or NO. For example, LOGICAL ("si", "si/no") returns TRUE.

- Data types such as RAW, MEMPTR, LVARBINARY, and so on return the Unknown value (?), but this is not considered an error.

See also STRING function, INTEGER function, DATE function

Logical values

Represent values of logical expressions.

Syntax

```
{ [ YES | TRUE ] | [ NO | FALSE ] }
```

YES | TRUE

A value that signifies a valid result for a logical expression.

NO | FALSE

A value that signifies an invalid result for a logical expression.

Note

You must use these values in a procedure even if alternate values are given in the FORMAT specification for a field or variable.

LOOKUP function

Returns an INTEGER value giving the position of an expression in a list. Returns a 0 if the expression is not in the list.

Syntax

```
LOOKUP ( expression , list [, character ] )
```
LOOKUP function

expression

A constant, field name, variable name, or expression that results in a character value that you want to look up within a list of character expressions. If the value of expression is the Unknown value (?), the result of the LOOKUP function is the Unknown value (?).

list

A character expression that contains the expression you name with the expression argument. Each entry in the list is separated with a delimiter. The list can be a variable of type CHARACTER or LONGCHAR. If list contains the Unknown value (?), LOOKUP returns the Unknown value (?).

count

A delimiter you define for the list. The default is a comma. This allows the LOOKUP function to operate on non-comma-separated lists.

Examples

This procedure prompts the user for a New England state. The LOOKUP function tests the value against the list of states stored in the stlist variable. If there is no match (the result is 0), the procedure displays a message. Otherwise, the procedure prompts the user for another New England state.

r-lookup.p

```abl
DEFINE VARIABLE stlist AS CHARACTER NO-UNDO
    INITIAL "ME,MA,VT,RI,CT,NH".
DEFINE VARIABLE state AS CHARACTER NO-UNDO FORMAT "x(2)".
REPEAT:
    SET state LABEL "Enter a New England state, 2 characters".
    IF LOOKUP(state, stlist) = 0 THEN
        MESSAGE "This is not a New England state".
    END.
```

The following example uses a different delimiter, which list all fields that have “sls” or “sales” as words in their standard Dictionary labels:

r-look2.p

```abl
FOR EACH _Field
    WHERE LOOKUP("sls",_Field._Label," ") > 0
        OR LOOKUP("sales",_Field._Label," ") > 0:
        DISPLAY _Field._Field-Name _Field._Label.
END.
```

Notes

- If expression contains a delimiter, LOOKUP returns the beginning of a series of entries in list. For example, LOOKUP("a,b,c","x,a,b,c") returns a 2.

- Most character comparisons are case insensitive in ABL. By default, upper-case and lower-case characters have the same sort value. However, you can define fields and variables as case sensitive (although it is not advised, unless strict ANSI SQL adherence is required). If the expression or list is defined as case sensitive, the comparison between them is also case sensitive and “Smith” does not equal “smith”.

730
The LOOKUP function is double-byte enabled. The specified expression can yield a string value that contains double-byte characters and the character delimiter can be a double-byte character.

The LOOKUP function always returns 0 if an expression is equal to a delimiter.

See also ENTRY function, ENTRY statement, INDEX function

LT or < operator

Returns a TRUE value if the first of two expressions is less than the second.

Syntax

```
expression { LT | < } expression
```

expression

A constant, field or variable name, or expression. The expressions on either side of the LT or <= must be the same data type, although one can be an integer and the other decimal.

Example

This procedure displays information for those Item records whose OnHand value is less than the Allocated value:

```
r-lt.p

FOR EACH Item NO-LOCK WHERE Item.OnHand < Item.Allocated:
END.
```

Notes

- By default, the AVM uses the collation rules you specify to compare characters and sort records. The collation rules specified with the Collation Table (-cpcoll) startup parameter take precedence over a collation specified for any database the AVM accesses during the session, except when the AVM uses or modifies pre-existing indexes. If you do not specify a collation with the -cpcoll startup parameter, the AVM uses the language collation rules defined for the first database on the command line. If you do not specify a database on the command line, the AVM uses the collation rules with the default name "basic" (which might or might not exist in the convmap.cp file).

- If either of the expressions is the Unknown value (?), then the result is the Unknown value (?); if both of the expressions are the Unknown value (?), then the result is FALSE.

- You can compare character strings with LT. Most such comparisons are case insensitive in ABL. That is, upper-case and lower-case characters have the same sort value. It is possible to define fields and variables as case sensitive (although it is not advised, unless strict ANSI SQL adherence is required). If either expression is a field or variable defined as case sensitive, the comparison is case sensitive and “Smith” does not equal “smith.”

- Characters are converted to their sort code values for comparison. Using the default case-sensitive collation table, all uppercase letters sort before all lowercase letters (for example, a is greater than Z, but less than b.) Note also that in character code uppercase A is less than [, \, ^, _ _, and ‘, but lowercase a is greater than these.
• You cannot compare data of different DATE, DATETIME, and DATETIME-TZ data types to each other using LT. You must first convert different date and datetime data types to the same data type before doing a comparison between them.

• You can use LT to compare a LONGCHAR variable to another LONGCHAR or CHARACTER variable. The variable values are converted to `-cpinternal` for comparison and must convert without error, or the AVM raises a run-time error.

• You cannot use LT to compare one CLOB field to another.
MATCHES operator

MATCHES operator

Compares a character expression to a pattern and evaluates to a TRUE value if the expression satisfies the pattern criteria.

Syntax

expression MATCHES pattern

expression

A CHARACTER or LONGCHAR expression that you want to check to see if it conforms with the pattern.

pattern

A character expression that you want to match with the string. This can include a constant, field name, variable name, or expression whose value is a character.

The pattern can contain wildcard characters: a period (.) in a particular position indicates that any single character is acceptable in that position; an asterisk (*) indicates that any group of characters is acceptable, including a null group of characters.

Example

This procedure displays customer information for all Customers whose Address ends in St. The procedure does not use an index for the Customer search in r-match.p.

r-match.p

FOR EACH Customer NO-LOCK WHERE Customer.Address MATCHES("*St"):  
END.

Notes

- MATCHES does not use index information when performing a comparison; it always scans the entire data table.

- MATCHES does not ignore trailing blanks as does the equal (EQ) comparison operator. Thus, “abc” does not match “abc  ” although they are considered equal.

- Most character comparisons are case insensitive in ABL. By default, all characters are converted to uppercase prior to comparisons. However, you can define fields and variables as case sensitive (although it is not advised, unless strict ANSI SQL adherence is required). If the expression preceding the MATCHES keyword is a field or variable defined as case sensitive, the comparison is case sensitive. In a case-sensitive comparison “SMITH” does not equal “Smith”.

- MATCHES converts a LONGCHAR variable value to -cpinternal prior to comparison. The variable must convert without error, or the AVM raises a run-time error.

- You cannot use MATCHES to compare one CLOB field to another.

- To specify either an asterisk (*) as a literal character rather than a wildcard character in the pattern, or a period (.) as a literal character, you must enter a tilde (~) before the character. However, if you specify the match pattern as a literal quoted string in a procedure file, you must enter each tilde as a double tilde (~~). The first tilde escapes the
MAXIMUM function

Comparisons two or more values and returns the largest value.

Syntax

```plaintext
MAXIMUM ( expression , expression [ , expression ] . . . )
```

expression

A constant, field name, variable name, or expression. If there is a mixture of decimal and integer data types, decimal type is returned.

Example

In this procedure, if the `CreditLimit` value is under 20,000, the procedure adds 10,000 to that value. Otherwise, the procedure sets `CreditLimit` to 30,000. The MAXIMUM function determines the greater of the original `CreditLimit` value and the new `cred-lim2` value.

```plaintext
DEFINE VARIABLE cred-lim2 AS DECIMAL NO-UNDO FORMAT ">>,>>9.99".
FOR EACH Customer NO-LOCK:
    cred-lim2 = IF Customer.CreditLimit < 20000 THEN
        Customer.CreditLimit + 10000 ELSE 30000.
    DISPLAY Customer.CreditLimit cred-lim2
    MAXIMUM(cred-lim2, Customer.CreditLimit)
    LABEL "Maximum of these two values".
END.
```

Notes

- When comparing character values, if at least one of the character fields is defined as case sensitive, then MAXIMUM treats all of the values as case sensitive for the sake of the comparisons. If none of the values is case sensitive, MAXIMUM treats lowercase letters as if they were uppercase letters.

- You cannot compare data of different DATE, DATETIME, and DATETIME-TZ data types to each other using MAXIMUM. You must first convert different date and datetime data types to the same data type before doing a comparison between them.

See also

- MINIMUM function

MD5-DIGEST function

Hashes the specified data using the RSA Message Digest Hash Algorithm (MD5), and returns a 16-byte binary message digest value as a RAW value.
MEMBER function

**Syntax**

```
MD5-DIGEST( data-to-hash [ , hash-key ] )
```

*data-to-hash*

The source data to hash. The data may be of type CHARACTER, LONGCHAR, RAW, or MEMPTR. If the data is a CHARACTER or LONGCHAR value, the AVM converts it to UTF-8 (which ensures a consistent value regardless of code page settings). To avoid this automatic conversion, specify a RAW or MEMPTR value.

*hash-key*

An optional key value to use in the hash operation. The key may be of type CHARACTER, LONGCHAR, RAW, or MEMPTR. If the key is a CHARACTER or LONGCHAR value, the AVM converts it to UTF-8 (which ensures a consistent value regardless of code page settings). To avoid this automatic conversion, specify a RAW or MEMPTR value. This key value is combined with the source data before the hash operation begins.

If the *hash-key* value contains a null character, the null character is included in the hash operation.

**See also**  
SHA1-DIGEST function

**MEMBER function**

Parses a reference to a member of an ABL r-code library and returns the simple member name.

**Syntax**

```
MEMBER( string )
```

*string*

A character expression (a constant, field name, variable or expression that results in a character value) whose value is the pathname of a file in an r-code library.

The MEMBER function parses a character string in the form `path-name<<member-name>>`, where *path-name* is the pathname of a library and *member-name* is the name of a file within the library, and returns *member-name*. The double angle brackets indicate that *member-name* is a file in a library. If the string is not in this form, the MEMBER function returns the Unknown value (?).

Use the MEMBER function with the SEARCH function to determine whether a file is in a library. If a data file is in a library, you must first extract the file from the library in order to read it. (See OpenEdge Deployment: Managing ABL Applications for more information on extracting a file from a library.) The SEARCH function returns a character string in the form `path-name<<member-name>>` if it finds a file in a library.

**Example**

This procedure prompts for the name of a file. Using this value, the procedure searches for the file. If it does not find the file, it displays a message and ceases operation. If it does find the file, it tests to see if the file is in a library. If so, the procedure displays the filename and the name of the library. Otherwise, the procedure displays the pathname of the file returned by SEARCH.
MESSAGE statement

Displays messages in the message area at the bottom of the window or in an alert box (or in an output stream—see the Notes section). By default, an area at the bottom line of the window is reserved for ABL system messages. An area above that is reserved for messages you display with the MESSAGE statement.

Syntax

```
MESSAGE
    [ COLOR color-phrase ]
    { expression | SKIP [ ( n ) ] } ...
    [ VIEW-AS ALERT-BOX
        [ alert-type ]
        [ BUTTONS button-set ]
        [ TITLE title-string ]
    ]
    [ { SET | UPDATE } field
        { AS datatype | LIKE field }|
        [ FORMAT string ]
        [ AUTO-RETURN ]
    ]
    [ IN WINDOW window ]
```

COLOR color-phrase

Displays a message using the color you specify with the COLOR phrase.

See also

LIBRARY function, SEARCH function
MESSAGE statement

For more information on color-phrase, see the COLOR phrase reference entry.

**Note:** The COLOR phrase does not have any effect in a Windows environment.

**expression**

An expression (a constant, field name, variable name, or expression) whose value you want to display in the message area. If expression is not character, it is converted to character before it is displayed. If you do not use this option, you must use either the SET or UPDATE option.

**SKIP \[ ( n ) \]**

Indicates a number (n) of blank lines to insert into the message. The value of n can be 0. If you do not specify n, or if n is 0, a new line is started unless the current position is already the start of a new line.

You can only use this option with the VIEW-AS ALERT-BOX option.

**VIEW-AS ALERT-BOX \[ alert-type \]**

Specifies that the message is displayed in an alert box rather than in the window message area. The value of alert-type determines the type of alert box. The possible values are:

- MESSAGE
- QUESTION
- INFORMATION
- ERROR
- WARNING

The type of alert box affects the visual representation of the box.

**BUTTONS button-set**

Specifies what sets of buttons are available within the alert box. The possible button sets are as follows:

- YES-NO
MESSAGE statement

- YES-NO-CANCEL
- OK
- OK-CANCEL
- RETRY-CANCEL

The name of each button set indicates the buttons in that set. For example, YES-NO contains two buttons labeled YES and NO; YES-NO-CANCEL contains three buttons labeled YES, NO, and CANCEL; OK contains a single button labeled OK. If you do not specify a button set, the default is OK.

TITLE title-string

Specifies a value to display in the title bar of the alert box.

SET field

Displays the expression you specified and SETs the field or variable you name. (It prompts the user for input and assigns the value entered to the field or variable.) You cannot test the field with the ENTERED function or the NOT ENTERED function.

UPDATE field

Displays the expression you specified and updates the field or variable you name. (It displays the current value of the field or variable, prompts for input, and assigns the value entered in the field or variable.) You cannot test the field with the ENTERED function or the NOT ENTERED function. For an alert box, field must be a LOGICAL variable. It sets the default button and returns the user’s choice. If the alert box has two buttons, they represent the values TRUE and FALSE, respectively. If the alert box has three buttons, they represent the values TRUE, FALSE, and the Unknown value (?), respectively.

AS datatype

Defines field as a variable of type datatype. You must use this option or the LIKE option if field has not been previously defined.

LIKE field

Defines the field specified in SET or UPDATE as a database field or a previously defined variable.

FORMAT string

The format that you want to use to display the field used in the SET or UPDATE option.

For more information on display formats, see OpenEdge Getting Started: ABL Essentials.

If you do not use the FORMAT option, ABL uses the defaults shown in Table 44.
Table 44: Default display formats

<table>
<thead>
<tr>
<th>Type of expression</th>
<th>Default format</th>
</tr>
</thead>
<tbody>
<tr>
<td>Field</td>
<td>Format from schema</td>
</tr>
<tr>
<td>Variable</td>
<td>Format from variable definition</td>
</tr>
<tr>
<td>Constant character</td>
<td>Length of character string</td>
</tr>
<tr>
<td>Other</td>
<td>Default format for the data type of the expression</td>
</tr>
</tbody>
</table>

Table 45 shows the default formats for the Other expression.

Table 45: Default data type display formats

<table>
<thead>
<tr>
<th>Data type</th>
<th>Default display format</th>
</tr>
</thead>
<tbody>
<tr>
<td>CHARACTER</td>
<td>x(8)</td>
</tr>
<tr>
<td>CLASS¹</td>
<td>N/A</td>
</tr>
<tr>
<td>DATE</td>
<td>99/99/99</td>
</tr>
<tr>
<td>DATETIME</td>
<td>99/99/9999 HH:MM:SS.SSS</td>
</tr>
<tr>
<td>DECIMAL</td>
<td>-&gt;&gt;&gt;,&gt;&gt;9.99</td>
</tr>
<tr>
<td>HANDLE²</td>
<td>&gt;&gt;&gt;&gt;&gt;&gt;9</td>
</tr>
<tr>
<td>INT64</td>
<td>-&gt;,&gt;&gt;,&gt;&gt;,&gt;&gt;9</td>
</tr>
<tr>
<td>INTEGER</td>
<td>-&gt;,&gt;&gt;,&gt;&gt;,&gt;&gt;9</td>
</tr>
<tr>
<td>LOGICAL</td>
<td>yes/no</td>
</tr>
<tr>
<td>MEMPTR³</td>
<td>See the footnote at the end of the table.</td>
</tr>
</tbody>
</table>
MESSAGE statement

Table 45:  Default data type display formats

<table>
<thead>
<tr>
<th>Data type</th>
<th>Default display format</th>
</tr>
</thead>
<tbody>
<tr>
<td>RAW(^3)</td>
<td>See the footnote at the end of the table.</td>
</tr>
<tr>
<td>RECID</td>
<td>&gt;&gt;&gt;&gt;&gt;&gt;&gt;9</td>
</tr>
<tr>
<td>ROWID(^3)</td>
<td>See the footnote at the end of the table.</td>
</tr>
</tbody>
</table>

1. For a class instance, ABL automatically invokes the `ToString()` method (provided by the `Progress.Lang.Object` class) on the object reference. Instead, you can also first explicitly convert the object reference to a displayable type using the `INT64` function, the `INTEGER` function, or the `STRING` function.

2. To display a HANDLE, you must first convert it using either the `INT64` or `INTEGER` function and display the result.

3. You cannot display a MEMPTR, RAW, or ROWID value directly. However, you can convert it to a character string representation using the `STRING` function and display the result. A ROWID value converts to a hexadecimal string, “0x`hexdigits`,” where `hexdigits` is any number of characters “0” through “9” and “A” through “F”. A MEMPTR or RAW value converts to decimal integer string.

AUTO-RETURN

Performs a carriage return when the field that is SET or UPDATED is full.

IN WINDOW window

Specifies the window in which the message is displayed.

Examples

In this procedure, if you enter the number of a Customer that does not exist, the procedure displays a message telling you the Customer does not exist. If the Customer does exist, the procedure displays the Name and SalesRep of the Customer.

r-msg.p

```
REPEAT:
    PROMPT-FOR Customer.CustNum.
    FIND Customer USING Customer.CustNum NO-ERROR.
    IF NOT AVAILABLE Customer THEN DO:
        MESSAGE "Customer with CustNum " INPUT Customer.CustNum 
        " does not exist. Please try another".
        UNDO, RETRY.
    END.
    ELSE
    END.
```

The following example uses two alert boxes:
In `r-altbox.p`, each time you select an item from the selection list, the procedure displays an alert box to ask if you want to delete the customer. If you choose the No button, then another alert box informs you that the record was not deleted.

### Notes

- The MESSAGE statement always sends messages to the current output destination. If the INPUT source is the terminal, the AVM displays messages in the window and also sends them to the current output destination. Compiler error messages also follow this convention.

- If you don’t want messages sent to the current output destination, redirect the output to a named stream. The AVM never writes messages to a named stream.

If you want to send output to a destination other than the terminal, and you do not want messages to appear on the terminal (and if you are not using the terminal as an input source), use one of the statements in Table 46.

#### Table 46: Suppressing messages to the terminal

<table>
<thead>
<tr>
<th>Operating system</th>
<th>Input from</th>
</tr>
</thead>
<tbody>
<tr>
<td>UNIX</td>
<td>INPUT FROM /dev/null</td>
</tr>
<tr>
<td>Windows</td>
<td>INPUT FROM NUL</td>
</tr>
</tbody>
</table>
Be sure to use the INPUT CLOSE statement to close the input source.

- The AVM automatically clears messages after any user interaction, such as a SET, UPDATE, or PAUSE statement, but not after a READKEY statement.

- In Microsoft Windows, the message text in VIEW-AS ALERT-BOX is limited to 511 bytes. If the text is longer than 511 bytes, it is truncated.

- When you use the MESSAGE SET or MESSAGE UPDATE statement to update a field, the AVM does not process any validation criteria defined for that field in the database. For example, if the validation criteria for the customer.name field is as follows:

  ```
  Valexp: name BEGINS "a"
  ```

  Use this statement:

  ```
  MESSAGE UPDATE name
  ```

  The AVM lets you enter any data, including data that does not start with the letter a, into the name field.

  Use the MESSAGE statement to display a message, but use the SET statement or UPDATE statement to let the user change the data in a frame rather than in the message area.

- If you are displaying a message to the message line and the combination of the text and field you name in a MESSAGE UPDATE statement exceeds the length of the message line, the AVM truncates the text to fit on the message line. For example:

  ```
  DEFINE VARIABLE myvar AS CHARACTER NO-UNDO FORMAT "x(60)".
  MESSAGE "abcdefghijklmnopqrstuvwxyz" UPDATE myvar.
  ```

  Here, the combination of the message text and the myvar variable exceeds 80 characters, so the AVM truncates the message text.

- Using the MESSAGE statement to display decimal values results in truncating the nonsignificant zeros to the right of the decimal point. For example:

  ```
  DEFINE VARIABLE amt AS DECIMAL NO-UNDO FORMAT ">>9.99" INITIAL 1.20.
  MESSAGE "Total" amt.
  ```

  The previous procedure displays the following message:

  ```
  "Total 1.2"
  ```

  Use functions such as STRING and DECIMAL to control the format of a display.
• If the APPL-ALERT-BOXES attribute of the SESSION system handle is TRUE, then all
  your messages are displayed in alert boxes. You can also direct all system messages to
  alert boxes by setting the SYSTEM-ALERT-BOXES attribute of the SESSION system
  handle to true. You can remove the message area for a window by setting its
  MESSAGE-AREA attribute to FALSE before it is realized.

• If you use the SET or UPDATE options in a graphical environment, the AVM
  automatically displays the message as an alert box.

• By default, all text in an alert box is displayed on a single line. If you want to break lines
  within the text, you must explicitly insert SKIP options into the message.

• If you use the OUTPUT TO statement to divert ABL error and warning messages to an
  output stream, ABL also diverts messages from the MESSAGE statement the same way.
  For more information, see the OUTPUT TO statement reference entry.

• The MESSAGE statement does not raise ERROR if the AVM fails to resolve an output
  expression. Instead, the empty string will be displayed at the specified output location.
  However, if the block containing the MESSAGE statement contains a CATCH block, then
  the MESSAGE statement will raise ERROR and you can handle that error with a
  compatible CATCH block.

• You can use the MESSAGE statement with an object reference for a class instance. In this
  case, the MESSAGE statement implicitly calls the ToString( ) method of the class to
  convert the specified object reference to a character value before it displays the result.

• For SpeedScript, the only valid options are: expression and SKIP.

**See also**  COLOR phrase, DECIMAL function, Format phrase, INTEGER function, MESSAGE-LINES
  function, STRING function

**MESSAGE-LINES function**

Returns, as an INTEGER value, the number of lines in the message area at the bottom of the
window.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```plaintext
MESSAGE-LINES
```

**Example**

The following example displays a message on each available message line:

```plaintext
r-messl.p

DEFINE VARIABLE ix AS INTEGER NO-UNDO.

DO ix = 1 TO MESSAGE-LINES:
   MESSAGE "This is message line" ix.
END.
```
**METHOD statement**

Defines a method of a class, declares a method prototype in an ABL interface, or overrides a method inherited from an ABL or .NET super class. A method is a class member that, when invoked by name, can execute code and return a value similar to a user-defined function. The description that follows begins with the general syntax for defining a method.

**Note:** This statement is applicable only when used in a class or interface definition (.cls) file.

**Syntax**

Use the following syntax to declare an interface method prototype:

```
METHOD [ PRIVATE | PROTECTED | PUBLIC ] [ STATIC | ABSTRACT ]
[ OVERRIDE ] [ FINAL ]
{ VOID | return-type } method-name
( [ parameter [ , parameter ] ... ] ) :
method-body
```

Use the following syntax to declare an abstract method prototype:

```
METHOD [ PUBLIC ]
{ VOID | return-type } method-name
( [ parameter [ , parameter ] ... ] ).
```

Use the following syntax to declare an abstract method prototype:

```
METHOD [ PROTECTED | PUBLIC ] [ OVERRIDE ] ABSTRACT
{ VOID | return-type } method-name
( [ parameter [ , parameter ] ... ] ).
```

```
[ PRIVATE | PROTECTED | PUBLIC ]
```

Specifies the access mode for this method. A PRIVATE method can be called only by the defining class. A PROTECTED method can be called by the defining class and any of its derived classes. A PUBLIC method can be called by:

- The defining class
- Any of its derived classes
- Any class or procedure that has access to a class instance that defines or inherits the method

Any piece of code can call a PUBLIC static method. The default access mode is PUBLIC.

When declaring an interface method prototype, the access mode for this method must be PUBLIC (the default).
When defining an abstract method, the access mode for the method cannot be PRIVATE.

If this method is defined with the OVERRIDE option, the access mode must not be more restrictive than the access mode defined for the overridden ABL or .NET super class method. ABL access modes correspond to inherited .NET access levels as follows:

- PROTECTED matches either the .NET protected or protected internal access level
- PUBLIC matches the .NET public access level

[ STATIC ]

Defines a method that is a static member of the class type for which it is defined and that is scoped to the ABL session where it is referenced. You can call an accessible static method in any piece of code.

Without this option, ABL defines an instance method that is scoped to a single instance of the class where it is defined. You can call any public instance method (abstract or non-abstract) in any procedure, or in any instance or static method defined inside or outside of the class where the instance property is defined. Any static method can call the public instance method only using an object reference to a class instance that defines the instance method as a member. If the referencing static method is defined in the same class as the public instance method, the class must instantiate itself in order to have access to an instance reference.

You can call a private or protected instance method only in other instance methods that are defined inside the same class or class hierarchy.

**Note:** You cannot use a class instance that is not equal to the THIS-OBJECT system reference to call a private or protected instance method that is defined in the same class, because PRIVATE and PROTECTED access modes are instance based in ABL. Thus, private and protected instance members are accessible only to other members of the same class instance, where as public instance members can be accessed from other instances of the same class, including the session “static instance” of the class.

For more information on the mechanism for calling methods of different access modes and scopes, see the reference entry for Class-based property access.

The STATIC option is not valid when you:

- Define or implement an abstract method
- Declare an interface method prototype
- Implement an interface method

[ ABSTRACT ]

Defines the method as an abstract member of the class type for which it is defined. The defining class type must also be abstract. If you define an abstract method, it has the following requirements:
You must specify the OVERRIDE option if an inherited method (abstract or otherwise) has the same name and signature.

You can specify either a PROTECTED or a PUBLIC access mode, depending on any inherited method you might be overriding.

The abstract method must be overridden and implemented in a derived class.

Any class definition for an instance method that includes the OVERRIDE option and does not include the ABSTRACT option defines a method implementation. If it also includes the ABSTRACT option, the inherited method remains or is redefined as abstract.

This option is not valid either when you define a static method or you declare an interface method prototype.

[ OVERRIDE ]

Specifies one of the following:

• This instance method overrides the behavior of another instance method inherited from an ABL or .NET class.

• This instance method implements, or redefines as abstract, an abstract method inherited from an ABL or .NET abstract class.

• This instance method redefines as abstract an implemented method inherited from an ABL or .NET class.

Note: A .NET abstract class is defined in C# with the abstract keyword.

• This static method redefines the behavior of another static method implemented in a super class.

When you specify OVERRIDE, the method signature must match the overridden method with respect to the name, return type, and the number, types, and modes of its parameters. In addition, the access mode cannot be more restrictive than the access mode of the super class method it overrides. When overriding a .NET method, the return type and parameters must also map appropriately to the inherited .NET method return type and parameters. For more information, see the description of the return-type and parameter options.

If you are overriding an inherited abstract method and you specify the ABSTRACT option, your overriding method is also defined as abstract, and it must be implemented in a class derived from the defining class. Note that you do not have to override an inherited abstract method that you want to remain abstract as long as the inheriting class is also abstract. However, doing so allows you to specify a less restrictive access mode for the abstract method.

If you do not specify the ABSTRACT option when overriding an inherited abstract method, your method definition implements the abstract method.

If you are overriding an inherited method that already has an implementation and you specify the ABSTRACT option, your overriding method redefines the inherited method as abstract, and it must, again, be implemented in a class derived from the defining class.
Note that to redefine an inherited method as abstract that already has an implementation, the defining class must also be abstract.

Note that instance methods do not override static methods and static methods do not redefine instance methods. For more information about overriding and redefining methods, see *OpenEdge Development: Object-oriented Programming*.

You can only override methods of a .NET super class that, in C# terms, are:

- Declared as `virtual` or `abstract`
- Declared as `public`, `protected` or `protected internal`
- Not declared as `static` or `sealed (FINAL)`

This option is not valid when you declare an interface method prototype.

```
[ FINAL ]
```

Indicates this method cannot be overridden or redefined by a method defined in an inheriting subclass.

This option is not valid either when you define an abstract method or when you declare an interface method prototype.

```
VOID
```

Indicates this method does not return a value.

```
return-type
```

Indicates the data type of the method return value. You can specify `return-type` as one of the following data types. For more information on each data type, see the Data types reference entry:

```
{ CHARACTER | COM-HANDLE | DATE | DATETIME | DATETIME-TZ | DECIMAL |
  | HANDLE | INT64 | INTEGER | LOGICAL | LONGCHAR | MEMPTR | RAW |
  | RECID | ROWID | AS-data-type |
  | [ CLASS ] object-type-name } [ EXTENT [ constant ] ]
```

```
AS-data-type
```

If you are defining the return type for a method that overrides a .NET super class method (abstract or otherwise) or implements a method defined in a .NET interface, `return-type` must specify the exact return type of the overridden or implemented .NET method. For a .NET mapped data type that is a default match for an ABL primitive type, you must use the default matching ABL data type, as shown in Table 23. (For example, `INTEGER` indicates a .NET System.Int32.) For a .NET mapped data type that is not a default match for one of the ABL primitive types, ABL provides a data type keyword (the `AS-data-type`) that you must use to explicitly indicate the required .NET data type, as shown in Table 24. (For example, `UNSIGNED-BYTE` indicates a .NET System.Byte.)
**Note:** At run time, a method return type defined using an `AS-data-type` keyword behaves in ABL like the corresponding ABL primitive type shown in Table 24. (For example, an UNSIGNED-BYTE behaves like an INTEGER.)

Also note that when overriding or implementing a .NET array return value, you must specify the .NET array object type (for example, "System.Int32[]" or "System.Byte[]"); you **cannot** use an ABL array equivalent (for example, INTEGER EXTENT or UNSIGNED-BYTE EXTENT).

**object-type-name**

Specifies the type name of an ABL or .NET class or interface. Specify an object type name using the syntax described in the Type-name syntax reference entry. With an appropriate USING statement, you can also specify a class or interface name alone, without the qualifying package or namespace.

If you are defining the return type for a method that overrides a .NET super class method (abstract or otherwise), or that implements a method defined in a .NET interface, **object-type-name** must specify the exact return type of the overridden or implemented .NET method. However, for .NET inner (nested) type, note the difference in the ABL syntax, which replaces the corresponding period (.) in the .NET object type with a plus (+) (see the Type-name syntax reference entry).

Also note that when overriding or implementing a .NET array return value, you must specify the .NET array object type (for example, "System.Drawing.Point[]"); you **cannot** use an ABL array equivalent (such as System.Drawing.Point EXTENT).

**[ CLASS ]**

If the specified class or interface type name conflicts with an abbreviation of a built-in primitive type name, such as INT for INTEGER, you must specify the CLASS keyword.

For a class or interface return value, ABL returns an object reference associated with the class or interface, not a class instance itself. For more information on object references, see the Class-based object reference reference entry.

**[ EXTENT [ constant ] ]**

Defines the return value as an array of data elements with a primitive or object data type. This option can specify an array return value as either determinate (has a defined number of elements) or indeterminate (has an undefined number of elements). To define a determinate array return value, specify the EXTENT option with the constant argument. This optional argument is an integer value that represents the number of elements in the array. To define an indeterminate array return value, specify the EXTENT option without the constant argument.

An indeterminate array return value can be in one of two states: fixed or unfixed, meaning it either has a fixed dimension or it does not. An indeterminate array return value has an unfixed dimension when first defined. You can fix the dimension of an indeterminate array return value by:

- Setting the number of elements in the array return value using the EXTENT statement
• Assigning a determinate array to the indeterminate array value, fixing it to the
dimension of the determinate array

• Passing array parameters to a procedure, user-defined function, or class-based
method, so that the indeterminate array value is the target for the passing of a
determinate array, fixing the indeterminate array to the dimension of the
determinate array

Once fixed, ABL treats a fixed indeterminate array as a determinate array.

If you do not use the EXTENT option (or you specify constant as 0), the return
value is not an array return value.

method-name

The method name. This name must be unique among all methods defined in the class
hierarchy of the defining class, unless the method:

• Includes the OVERRIDE option to override an inherited method.

• Overloads a method in the defining class or in any super class within its inherited
class hierarchy. In this case, the parameter list must differ from that of every other
method with the same name in the defining class, and it must differ from that of every
other method with the same name defined in every super class of the defining class.

Note: Members of a class are grouped into six namespaces, including
buffers/temp-tables, methods, variables/properties/events, ProDataSets, queries,
and data-sources. Methods defined as members of a class share the same
namespace. There can be only one class member in this namespace with a given
name.

If the method is defined in a class that is derived from a .NET class, other
restrictions on method-name apply. For more information, see the Notes in this
reference entry.

( [ parameter [ , parameter ] ... ] )

Defines zero or more parameters of the method.

If this method is one of several overloaded methods, the parameter list must be unique
among all public and protected methods defined in the class hierarchy of the defining
class. This uniqueness can be established using a different combination of number, data
types, or modes for the parameters. Note that both instance and static methods overload
one another within the class hierarchy.

If this method implements an interface method prototype or overrides an inherited method
(using the OVERRIDE option), the parameter list must match the parameter list of the
interface method prototype or a public or protected method with the same name that is
inherited from a super class.

If the method implements a .NET interface method prototype or overrides an inherited
.NET method (abstract or otherwise), you must explicitly map any .NET mapped types
specified for parameters of the .NET method (see Table 24). Note that at run time, any
explicitly mapped parameter behaves like the corresponding ABL primitive type.
For more information on the syntax of parameter, establishing uniqueness for method overloading, and on mapping .NET parameter types, see the Parameter definition syntax reference entry.

method-body

The body for a method implementation. For an interface method prototype or an abstract method, you cannot specify method-body. For more information about declaring method prototypes in an interface, see the INTERFACE statement reference entry.

Define method-body using the following syntax:

**Syntax**

```
method-logic
  ...
  [ catch-block [ catch-block ... ] ]
  [ finally-block ]
END [ METHOD ].
```

method-logic

The logic of the method. This logic can contain most ABL statements that are allowed within a PROCEDURE block, including class-related statements. The exception is that if the method returns a value, its logic must not reference, either directly or indirectly, statements that block for input (namely, the CHOOSE, INSERT, PROMPT-FOR, READKEY, SET, UPDATE, and WAIT-FOR statements).

If you define the method to return a value of the data type specified by return-type, you can execute the RETURN statement to set a value of that data type to return at run time. If return-type is defined as a .NET array of mapped types (for example, "System.Byte[]"), you must return an object reference of the specified .NET array of mapped types in the RETURN statement. You cannot return an ABL array of a type that maps to the .NET array type (for example, INTEGER EXTENT) or the AVM raises a run-time error. If you do not execute any RETURN statement for return-type in the method-logic, the method returns the Unknown value (?) as its return value.

If you are defining an instance method with the OVERRIDE option, you can also call the overridden implementation of this method in the class hierarchy using the SUPER system reference. You can also optionally call any instance method defined in the same class using the THIS-OBJECT system reference.

If you are defining a static method, you cannot access any instance members of a class (including the defining class) nor can you use the SUPER and THIS-OBJECT system references. From a static method, you can access only other static members of a class and the local variables or other local data elements of the method.

Each logic statement must end with a period.
catch-block

Specifies a CATCH statement that defines error handling code for one or more error types. A DO block does not have any default error handling. Therefore, a DO block must have error handling options specified such that it becomes an undoable block. Otherwise, ABL generates a compiler warning. For more information on catch-block, see the CATCH statement reference entry.

finally-block

Specifies a FINALLY statement that defines the processing that must occur after all other processing in the block occurs. For more information on finally-block, see the FINALLY statement reference entry.

METHOD

Specifies the end of the method body definition. You must end the method body definition with the END statement.

Examples

The following example shows the definition of an instance method in a class (which might implement a method prototype declared in an interface, as depicted in the second example):

```abl
METHOD PUBLIC CHARACTER GetCustomerName (INPUT inCustNum AS INTEGER):
    FIND ttCust WHERE ttCust.CustNum = inCustNum NO-ERROR.
    IF AVAILABLE ttCust THEN
        RETURN ttCust.CustName.
    ELSE
        RETURN ?.
    END METHOD.
```

The following example shows the definition of a method prototype declaration in an interface (which can be implemented by an instance method definition in a class, as depicted in the first example):

```abl
INTERFACE acme.myObjs.Interfaces.ICustObj:
    METHOD PUBLIC CHARACTER GetCustomerName (INPUT inCustNum AS INTEGER).
END INTERFACE.
```

For more examples of method definitions, including static and abstract methods, see the descriptions of r-CustObj.cls, r-CustObjStatic.cls, and r-CustObjAbstract.cls in the CLASS statement reference entry.

Notes

- You can terminate a METHOD statement with either a period (.) or a colon (:), but typically use a colon (:) for a method definition (in a class) and a period (.) for a method prototype (in an interface).

- A complete method definition must begin with the METHOD statement and end with the END statement.

- A method can access any data members and properties in its defining class including all PROTECTED and PUBLIC data members and properties defined anywhere in its
METHOD statement

inherited class hierarchy. For more information on referencing data members and properties, see the reference entries for a Class-based data member access and a Class-based property access.

- A method of a class can invoke another method of a class (instance or static, as appropriate), as well as an internal or external procedure or a user-defined function. Similarly, a procedure or user-defined function can invoke a method of a class. Note that if method-name is an ABL reserved keyword, you might need to use the THIS-OBJECT system reference or Type-name syntax to call the method. For more information on referencing and invoking methods, see the reference entry for a Class-based method call.

- Local variables and other data elements defined within a method are scoped to the end of the method definition. The values of local variables and data elements do not persist across method invocations; they are re-initialized each time you invoke the method. However, if you define a local variable within a method using the same name as a data member or property within the class hierarchy, the local variable takes precedence over the data member or property for the duration of the method.

- When defining local variables and other data elements for any method, even one that overrides or implements a .NET method, you cannot define these elements using an AS data type (see Table 24). You must use an ABL data type like any other method definition. The ABL data that you assign to or from a given .NET method parameter must be assignment compatible with the .NET type, as in all other contexts.

- You cannot specify the PRIVATE, PUBLIC, or PROTECTED access mode for variable definitions in a method.

- You cannot define SHARED objects, work tables, temp-tables, or ProDataSet objects within the body of a method.

- ABL implements primitive and array parameters of methods as NO-UNDO variables.

- You can handle application errors in a method as in any ABL block. By executing a RETURN ERROR action at the block level or a THROW action at the block level with the presence of a ROUTINE-LEVEL ON ERROR UNDO, THROW statement, the AVM returns the ERROR condition to the statement that invoked the method. If a RETURN ERROR also includes the option to return a character string value, or you set the ReturnValue property of a Progress.Lang.AppError object that you THROW, you can get this value using the RETURN-VALUE function following the statement that invoked the method or in a CATCH block that catches the Progress.Lang.AppError object. For more information, see OpenEdge Development: Object-oriented Programming.

- You cannot override an inherited .NET generic method. However, you can create a non-generic ABL method of the same name (without a type parameter list).

- You cannot override the following .NET methods:
  - DestroyHandle( )
  - Dispose( )
  - Finalize( )
  - GetHashCode( )
In .NET, these methods are overridable. However, OpenEdge defines these methods as FINAL for an ABL session. Instead of overriding .NET methods (such as `Dispose()` that destroy or otherwise clean-up .NET resources, always use a destructor in the ABL class to manage class clean-up using these methods, even when inheriting from a .NET class. Similarly, if you want to return an ABL-processed value generated by `GetHashCode()`, create a separate ABL method that calls `GetHashCode()` to return the value.

- When you define a method in an ABL class that inherits a .NET class, you **cannot** define `method-name` as any of the following reserved method names (case insensitive) or ABL raises a compile-time error:

  - `Get_property-name()` — Where `property-name` is the name of a property (including any default indexed property) defined by the .NET super class

  **Note:** For default indexed properties, `property-name` is usually `Item`.

  - `Set_property-name()` — Where `property-name` is the name of a property (including any default indexed property) defined by the .NET super class
  - `Add_event-name()` — Where `event-name` is the name of an event defined by the .NET super class
  - `Remove_event-name()` — Where `event-name` is the name of an event defined by the .NET super class

- When you raise error from within an ABL method that overrides a .NET method or implements a .NET method defined in a .NET interface, if the method is called from .NET, and ABL error options raise the error out of the method block, ABL returns a .NET `System.Exception` to the caller. If the error is raised by executing a `RETURN ERROR` with the optional error string, the `Message` property of the `System.Exception` describes the operation where the error occurred, but the error string is available only to the ABL session, using the `RETURN-VALUE` function. If the error is raised by executing a `RETURN ERROR` with an optional ABL error object or by executing an `UNDO`, `THROW`, the `System.Exception.Message` property includes both a description of the operation where the error occurred and any messages from the ABL error object. If the error is fatal, the AVM responds as for any ABL class, generating a protrace file and exiting the session.

**MINIMUM function**

Compares two or more values and returns the smallest.

**Syntax**

```
MINIMUM ( expression , expression [ , expression ] ... )
```
MODULO operator

**expression**

A constant, field name, variable name, or expression. If there is a mixture of decimal and integer data types, decimal type is returned.

**Example**

This procedure prompts the user for an item number and how many of the item they want. If the number of items a user wants (stored in the want variable) is the minimum of the want variable and the OnHand field, the procedure displays an “enough in stock” message. Otherwise, the procedure displays a “not enough in stock” message.

```
r-minimum.p

DEFINE VARIABLE want NO-UNDO LIKE on-hand LABEL "How many do you want?".
DEFINE VARIABLE ans AS LOGICAL NO-UNDO.
REPEAT:
  PROMPT-FOR Item.ItemNum want.
  FIND Item NO-LOCK USING Item.ItemNum.
  ans = FALSE.
  IF MINIMUM(INPUT want, Item.OnHand) = INPUT want THEN DO:
    MESSAGE "We have enough" Item.ItemName "in stock."
    MESSAGE "Any other items to check?" UPDATE ans.
    IF NOT ans THEN LEAVE.
  END.
  ELSE DO:
    MESSAGE "We only have" Item.OnHand Item.ItemName "in stock."
    MESSAGE "Any other items to check?"
    UPDATE ans.
    IF NOT ans THEN LEAVE.
  END.
END.
```

**Notes**

- When comparing character values, if at least one of the character fields is defined as case sensitive, then MINIMUM treats all of the values as case sensitive for the sake of the comparisons. If none of the values is case sensitive, MINIMUM treats lowercase letters as if they were uppercase letters.

- You cannot compare data of different DATE, DATETIME, and DATETIME-TZ data types to each other using MINIMUM. You must first convert different date and datetime data types to the same data type before doing a comparison between them.

**See also** MAXIMUM function

MODULO operator

Determines the remainder after division.

**Syntax**

```
expression MODULO base
```

**expression**

An integer expression. If the expression could result in a decimal value, then that value will be rounded before the MODULO operation occurs. This may or may not produce a result that is sensible for your business logic. For code readability, such an expression should be explicitly converted to an integer expression with attention to whether or not a
rounded or truncated integer is correct for your application. See the INTEGER, ROUND, and TRUNCATE functions

`base`

A positive integer expression that is the modulo base. For example, angles measured in degrees use a base of 360 for modulo arithmetic. 372 MODULO 360 is 12.

**Example**

This procedure determines the number of trucks required to ship a given quantity of material, and how much material is left over from a less than full truck load:

```plaintext
r-modulo.p

REPEAT:
  SET qty-avail AS INTEGER LABEL "Qty. Avail."
  SET std-cap AS INTEGER LABEL "Std. Truck Capacity"
  DISPLAY TRUNCATE(qty-avail / std-cap,0) FORMAT ">,>>9" LABEL "# Full Loads"
  qty-avail MODULO std-cap LABEL "Qty. Left"
END.
```

**Note**

The *expression* must be greater than 0 for MODULO to return a correct value.

**See also**

INTEGER function, ROUND function, TRUNCATE function

---

**MONTH function**

Evaluates a date expression and returns a month INTEGER value from 1 to 12, inclusive.

**Syntax**

```plaintext
MONTH ( date )

MONTH ( datetime-expression )
```

*date*

A date expression where you want a month value.

*datetime-expression*

An expression that evaluates to a DATETIME or DATETIME-TZ. The MONTH function returns the month of the date part of the DATETIME or DATETIME-TZ value.

**Example**

This procedure displays all the Orders that have a PromiseDate in a month that has passed, and whose ShipDate field is the Unknown value (?), which is the initial value of the ShipDate field:
MTIME function

Returns an INTEGER value representing the time in milliseconds. If the MTIME function has no arguments, it returns the current number of milliseconds since midnight (similar to TIME, which returns seconds since midnight).

Syntax

```plaintext
MTIME ([datetime-expression])
```

**datetime-expression**

An expression that evaluates to a DATETIME or DATETIME-TZ. The MTIME function returns the time portion of `datetime-expression` in milliseconds.

If `datetime-expression` is a DATETIME-TZ, the MTIME function returns the local time relative to the time zone of the DATETIME-TZ value. For Example, a DATETIME-TZ field, `fdt`, is created in London (time zone UTC+00:00) with a value of May 5, 2002 at 7:15:03.002 am. MTIME(`fdt`) returns 26,103,002, regardless of the session’s time zone.

The MTIME function gets the current system time of the client or server machine that serves as the time source for applications running during the ABL session (specified by the TIME-SOURCE attribute).

See also

ADD-INTERVAL function, DATE function, DATE-FORMAT attribute, DATETIME function, DATETIME-TZ function, DAY function, ETIME function, INTERVAL function, ISO-DATE function, MTIME function, NOW function, TIME function, TIMEZONE function, TODAY function, WEEKDAY function, YEAR function, YEAR-OFFSET attribute

NE or <> operator

Compares two expressions and returns a TRUE value if they are not equal.
NE or <> operator

Syntax

```
expression { NE | <> } expression
```

expression

A constant, field name, variable name, or expression. The expressions on either side of the NE or must be of the same data type.

Example

This procedure displays information for all items that appear in the catalog. (The CatPage field is not equal to the Unknown value (?) or 0.)

```
r-ne.p
FOR EACH Item NO-LOCK WHERE Item.CatPage <> ? AND Item.CatPage <> 0:
  DISPLAY Item.ItemNum Item.ItemName Item.CatPage
  WITH TITLE "Catalog Items" USE-TEXT.
END.
```

Notes

- By default, the AVM uses the collation rules you specify to compare characters and sort records. The collation rules specified with the Collation Table (-cpcoll) startup parameter take precedence over a collation specified for any database the AVM accesses during the session, except when the AVM uses or modifies pre-existing indexes. If you do not specify a collation with the -cpcoll startup parameter, the AVM uses the language collation rules defined for the first database on the command line. If you do not specify a database on the command line, the AVM uses the collation rules with the default name "basic" (which might or might not exist in the convmap.cp file).

- If one of the expressions has the Unknown value (?) and the other does not, the result is TRUE. If both have the Unknown value (?), the result is FALSE. For SQL, however, if one or both expressions have the Unknown value (?), then the result is the Unknown value (?).

- You can compare character strings with NE. Most character comparisons are case insensitive in ABL. That is, all characters are converted to uppercase prior to comparisons. However, it is possible to define fields and variables as case sensitive (although it is not advised, unless strict ANSI SQL adherence is required). If either expression is a field or variable defined as case sensitive, the comparison is case sensitive and “Smith” does not equal “smith”.

- Characters are converted to their sort code values for comparison. Using the default case-sensitive collation table, all uppercase letters sort before all lowercase letters (for example, a is greater than Z, but less than b.) Note also that in character code uppercase A is less than [.\^], and ‘, but lowercase a is greater than these.

- You cannot compare data of different DATE, DATETIME, and DATETIME-TZ data types to each other using NE. You must first convert different date and datetime data types to the same data type before doing a comparison between them.

- You can use NE to compare one BLOB field to another. The AVM performs a byte-by-byte comparison.

- You can use NE to compare a LONGCHAR variable to another LONGCHAR or CHARACTER variable. The variable values are converted to -cpinternal for comparison and must convert without error, or the AVM raises a run-time error.
• You can use NE to compare a CLOB field only to the Unknown value (?).

NEW function (classes)

Creates an instance of a class (object) and returns an object reference to that instance. You can use this object reference to access the PUBLIC data members, properties, and methods of the instance. For more information on object references, see the reference entry for a Class-based object reference.

Syntax

```
NEW object-type-name ( [ parameter [ , parameter ] ... ] )
```

`object-type-name`

Specifies the type name of the ABL or .NET class you want to instantiate. Specify a class type name using the syntax as described in the Type-name syntax reference entry. If `object-type-name` specifies a .NET object, it can be most any .NET class, with a few restrictions. For more information, see the Notes of this reference entry.

If, without casting, you assign the NEW function value to a target data element, or pass the NEW function as input to a target routine parameter, `object-type-name` must specify one of the following classes:

• The same class type that is defined for the target
• A subclass of the class type that is defined for the target
• A class type that implements the interface type defined for the target

If `object-type-name` specifies one of the following kinds of object types, ABL raises a compiler error:

• An interface type
• An abstract class type

` ( [ parameter [ , parameter ] ... ] )`

Specifies zero or more parameters passed to a PUBLIC instance constructor that is defined for the class. You must provide the parameters identified by the specified constructor, matched with respect to number, data type, and mode. To invoke a constructor that is overloaded in the class, you must specify sufficient information for each `parameter` to disambiguate it from all other constructors in the class. Otherwise, ABL raises an error identifying the ambiguity.

For information on the parameter passing syntax and disambiguating overloaded constructors, see the Parameter passing syntax reference entry.

For information on defining a constructor for a class, see the `CONSTRUCTOR statement` reference entry.

Examples

The following example shows how the NEW function can instantiate a class within an expression:
This code fragment instantiates a Progress.Lang.Object in order to check if the string value returned from its ToString() method begins with "Progress", and displays a message if it does.

The following example shows three (3) invocations of the NEW function.

```plaintext
r-newclass.p

ROUTINE-LEVEL ON ERROR UNDO, THROW.

FUNCTION ClassFunc RETURNS CLASS Progress.Lang.Object
  (INPUT iVal AS INTEGER):
  MESSAGE "iVal = " iVal VIEW-AS ALERT-BOX.
  IF iVal MODULO 2 = 0 THEN
    RETURN NEW Progress.Lang.Object().
  ELSE
    RETURN ?.
  END IF.
END FUNCTION.

RUN DisplayClass( NEW Progress.Lang.Object() ).

PROCEDURE DisplayClass:
  DEFINE VARIABLE cClass1 AS CHARACTER NO-UNDO.
  DEFINE VARIABLE cClass2 AS CHARACTER NO-UNDO.
  cClass1 = rObj:ToString().
  /* The ToString() call errors on an odd RANDOM input value */
  cClass2 = ( ClassFunc( RANDOM(1,100) ) ):ToString().
  MESSAGE "The " cClass1 " and " cClass2 " instances have the same class type." VIEW-AS ALERT-BOX.
  CATCH e AS Progress.Lang.SysError:
  END CATCH.
END PROCEDURE.
```

This `r-newclass.p` procedure runs an internal procedure (`DisplayClass`) that displays a message showing the ToString() values of two different objects instantiated as the same class type (Progress.Lang.Object). However, one of these objects is instantiated within a user-defined function (`ClassFunc`) that returns a valid object reference or the Unknown value (?) in order to generate an error, depending on the input value of a RANDOM function.

When a valid object reference is returned, it is used to access the ToString() method of the instance in an expression. When the Unknown value (?) is returned, this generates a run-time error when used as an object reference. The procedure then catches the error and responds by throwing a Progress.Lang.AppError object that is also instantiated by a NEW function invoked in an expression, and the error text is displayed as an error message when run in the OpenEdge Editor.

**Notes**

- When you create an instance of a class, ABL invokes the specified constructor for the class. At this time, the object instance gets its own copy of the data members and properties defined in the class and in all classes within its inherited class hierarchy. In
addition, the object instance is added to the session object chain referenced by the FIRST-OBJECT attribute or LAST-OBJECT attribute of the SESSION system handle.

- If you invoke the NEW function in an expression, the class constructor cannot execute (directly or indirectly) any input-blocking statements, such as the WAIT-FOR statement (ABL only) or UPDATE statement. (The MESSAGE statement is the exception to this rule.) Otherwise, the AVM raises a run-time error. The only context in which the NEW function can call a constructor that executes these input-blocking statements is when you invoke the function in a NEW statement.

- The ABL Virtual Machine (AVM) automatically deletes (garbage collects) any class instance that you create with the NEW function some time after no reference to that object exists in the ABL session. However, you can force any class instance to be deleted immediately by using the DELETE OBJECT statement. For more information on garbage collection for class instances, see the DELETE OBJECT statement reference entry.

- You can assign the object reference value returned by the NEW function to an ABL data element (or target of a passed parameter) defined as a class type or interface type when the destination data element (or parameter target) is defined as the same class as, as a super class of, or as an interface implemented by the instantiated class. In any case, the target data element retains its defined class or interface type. For more information on assigning object references to ABL data elements, see the NEW statement and Assignment (=) statement reference entries.

- You can use an object reference as a parameter or return type for methods, internal and external procedures, and user-defined functions (see the example).

- You cannot pass an object reference as a parameter to an AppServer; nor can you pass a temp-table containing an object reference field as a parameter to an AppServer.

- You can only access PUBLIC data members, properties, or methods using an object reference. You cannot access PRIVATE or PROTECTED class members using an object reference. If you want to make PRIVATE or PROTECTED class members available outside of a class instance where they are defined, you must provide PUBLIC methods or properties to do so. For information on accessing PUBLIC data members, properties, or methods using an object reference, see the Class-based object reference entry.

- Class-based object instances are not associated with handle-based objects, such as socket or procedure objects, and object references are not compatible with object handles. Thus, for example, you cannot use an object reference in any statement or function that returns a value of type HANDLE, and you cannot pass a procedure handle to a method that expects an object reference.

- You can compare two object references for equality using the EQ (=) operator, which determines if two object references are referencing the same object instance. Two object references can be equal even when you define their data types for different classes in the same class hierarchy as long as they each point to the same class instance. So, if ClassA is a super class of ClassB, and two object references point to the same ClassB instance, if one object reference is defined with the ClassA data type and the other object reference is defined with the ClassB data type, the two object references are equal. However, if the ClassA object reference points to a different class instance than the ClassB object reference, the two object references are not equal. Two object references are also equal if they are both set to the Unknown value (?).
NEW function (record buffers)

You can use the Equals( ) method in the Progress.Lang.Object class to compare the data members and properties of two object references, as long as this class provides an implementation of the Equals( ) method.

If object-type-name specifies a .NET object, note that in ABL you cannot instantiate the following .NET classes:

- Any .NET class that is defined in the default namespace, that is, where the class name is the complete object type name
- System.Threading.Thread or any class derived from it
- System.Delegate or any delegate type derived from it

This function can raise errors during the execution of constructors for the class being instantiated, or for any class in its inherited class hierarchy. For example:

- A constructor in the class hierarchy executes the RETURN statement with the ERROR option or the UNDO statement with the THROW or RETURN ERROR options.
- The class definition file for the class, a super class, or an interface could not be found.
- The run-time parameters of the constructor for the class, or a constructor for a class in the inherited class hierarchy, are not compatible.

When the AVM encounters one of these errors, and the constructor cannot create the class instance or its inherited class hierarchy, the AVM automatically invokes the destructor for any class that has already been constructed while building the class hierarchy for the object.

For more information on errors raised by instantiating classes, see OpenEdge Development: Object-oriented Programming.

Any errors returned during class instantiation, including application errors returned by constructors executing RETURN ERROR or UNDO, THROW, are handled by the statement that invokes the NEW function. In any case, if a RETURN ERROR in the constructor of the instantiating class also returns an optional character string value, this value is available using the RETURN-VALUE function following the statement where this NEW function appears.

**See also**

**NEW function (record buffers)**

Checks a record buffer and returns a TRUE value if the record in that buffer is newly created. If the record was read from the database, NEW returns a FALSE value.

**Syntax**

| NEW record |
NEW statement

record

The name of the record buffer you want to check with the NEW function.

To use the NEW function with a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

Example

This procedure enters new Orders, optionally creating a Customer record if one does not exist. The NEW function is later used to select alternate processing depending if a Customer is newly created or already exists.

r-newrecord.p

```abl
REPEAT:
PROMPT-FOR Customer.CustNum.
FIND Customer USING Customer.CustNum NO-ERROR.
IF NOT AVAILABLE Customer THEN
  DO WITH FRAME newcus:
    MESSAGE "Creating new customer".
    CREATE Customer.
    ASSIGN Customer.CustNum.
  END.

  CREATE Order.
  Order.CustNum = Customer.CustNum.
  IF NEW Customer THEN DO:
    UPDATE Order.OrderNum Order.PromiseDate.
    Order.Terms = "COD".
    DISPLAY Order.Terms.
  END.
  ELSE
    UPDATE Order.OrderNum Order.PromiseDate Order.Terms.
  END.
```

Note

The NEW function returns a TRUE value only during the transaction in which the record is created. If the scope of the record is greater than the transaction in which the record is created, the NEW function returns a FALSE value outside the transaction.

See also

AVAILABLE function, FIND statement, LOCKED function, Record phrase

NEW statement

Creates an instance of a class (object) using the NEW function and assigns its object reference to an appropriately defined ABL data element. Once assigned, you can use the object reference to access this class instance and its PUBLIC data members, properties, and methods. For more information on object references, see the reference entry for a Class-based object reference:

Syntax

```
object-reference = new-function [ NO-ERROR ]
```
**NEW statement**

**object-reference**

The name of an ABL data element to which you want to assign the object reference of a new instance of the class specified by `new-function`. This data element must be defined as a compatible class or interface type and can be one of the following:

- A temp-table field defined as a Progress.Lang.Object class type using the DEFINE TEMP-TABLE statement
- A variable scoped to the current procedure, user-defined function, or method of a class or an accessible class-based variable data member defined as a class or interface type using the DEFINE VARIABLE statement
- A parameter defined as a class or interface type for the current procedure, user-defined function, or method of a class using an appropriate DEFINE PARAMETER statement or Parameter definition syntax
- An accessible and writable class-based property defined as a class or interface type using the DEFINE PROPERTY statement

To be compatible, the object type of `object-reference` must be:

- The same class type as the class instantiated by `new-function`
- A super class of the class instantiated by `new-function`
- An interface that is implemented by the class instantiated by `new-function`

**new-function**

An invocation of the NEW function, which creates an instance of a specified class and returns an object reference to that instance. This is the syntax for the NEW function, where `object-type-name` must specify a class type consistent with the object type of `object-reference`:

**Syntax**

```
NEW object-type-name ( [ parameter [ , parameter ] ... ] )
```

The `parameter` list specifies the class constructor that is used to instantiate the class. For more information on the syntax and operation of the NEW function, see the NEW function (classes) reference entry.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

For the NEW statement, after the statement completes, `object-reference` remains unchanged. If a RETURN statement or an UNDO statement with the THROW or RETURN ERROR options in a constructor raises ERROR and also returns an error string,
you can obtain this string value after the assignment statement completes using the RETURN-VALUE function.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE(message-num) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Example**

The following code fragment shows the definition of a variable that is assigned to the object reference for a new class instance:
Notes

- When executed in the context of the NEW statement, the class constructor invoked by `new-function` can execute input-blocking statements (such as the WAIT-FOR statement (ABL only)). This is different from a NEW function executed in the context of an expression, which cannot invoke a constructor that executes input-blocking statements.

- After the assignment, `object-reference` contains a copy of the object reference value returned by `new-function`, which points to the same object instance, not a copy of the object created by `new-function`.

- Although you can assign an object reference to a temp-table field defined as a Progress.Lang.Object class type, you cannot assign an object reference to a field in a database table. For more information, see *OpenEdge Development: Object-oriented Programming*.

- This statement can raise errors during the execution of constructors for the class being instantiated by `new-function`, or for any class in its inherited class hierarchy. For example:
  - A constructor in the class hierarchy executes the RETURN statement with the ERROR option or the UNDO statement with the THROW or RETURN ERROR options.
  - The class definition file for the class, a super class, or an interface could not be found.
  - The runtime parameters of the constructor for the class, or a constructor for a class in the inherited class hierarchy, are not compatible.

When the AVM encounters one of these errors, and the constructor cannot create the class instance or its inherited class hierarchy, the AVM automatically invokes the destructor for any class that has already been constructed while building the class hierarchy for the object.

For more information on errors raised by instantiating classes, see *OpenEdge Development: Object-oriented Programming*.

- The ABL Virtual Machine (AVM) automatically deletes (garbage collects) any class instance that you create with the NEW statement some time after no reference to that object exists in the ABL session. However, you can force any class instance to be deleted immediately by using the DELETE OBJECT statement. For more information on garbage collection for class instances, see the DELETE OBJECT statement reference entry.

NEXT statement

Goes directly to the END of an iterating block and starts the next iteration of the block.
NEXT-PROMPT statement

Syntax

```plaintext
NEXT [ label ]
```

**label**

The name of the block for which you want to start the next iteration. If you do not name a block, the AVM starts the next iteration of the innermost iterating block that contains the NEXT statement.

**Example**

The FOR EACH block in this procedure reads a single Customer record on each iteration of the block. If the SalesRep field of a Customer record does not match the SalesRep value supplied to the PROMPT-FOR statement, the NEXT statement causes the AVM to do the next iteration of the FOR EACH block, bypassing the DISPLAY statement.

```plaintext
r-next.p
```

```
PROMPT-FOR Customer.SalesRep LABEL "Enter salesman initials"
   WITH SIDE-LABELS CENTERED.
FOR EACH Customer:
   IF Customer.SalesRep <> INPUT Customer.SalesRep THEN NEXT.
   WITH CENTERED USE-TEXT.
END.
```

**See also**

LEAVE statement

---

NEXT-PROMPT statement

Specifies the field in which you want to position the cursor during the next input operation that involves that field in a frame.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```plaintext
NEXT-PROMPT field [ frame-phrase ]
```

**field**

Indicates the name of the input field in which you want to place the cursor the next time the user supplies input to the frame. If the field you name is not an input field in the frame, the AVM disregards the NEXT-PROMPT statement.

**frame-phrase**

Specifies the overall layout and processing properties of a frame. For more information on `frame-phrase`, see the Frame phrase reference entry.

**Example**

This procedure lets you update Customer information. If you do not enter a value for Customer.Contact, the AVM positions the cursor in the Contact field when the UPDATE statement is processed following the UNDO, RETRY of the FOR EACH block.
**NEXT-PROMPT** is useful in an EDITING phrase because it can dynamically reposition the cursor depending on input from the user.

- When you have to do complex field checking that you are unable to do in a Dictionary validation expression or in a VALIDATE option of the Frame phrase, use NEXT-PROMPT to position the cursor after detecting an error.

- If the next data entry statement involving the frame specified with NEXT-PROMPT does not use the indicated NEXT-PROMPT field, then the AVM ignores the NEXT-PROMPT statement.

- The NEXT-PROMPT statement can affect default frame layout. In this procedure, the AVM prompts for a and b (in that order):

```
r-nprmp.p
```

``` diplomatscript
FOR EACH Customer:
    UPDATE Customer WITH 2 COLUMNS.
    IF Customer.Contact EQ "" THEN DO:
        MESSAGE "You must enter a contact".
        NEXT-PROMPT Customer.Contact.
        UNDO, RETRY.
    END.
END.
```

However, if you include NEXT-PROMPT b before the update statement, as shown in the following procedure, the AVM prompts for b first and a second:

```
r-nextp.p
```

``` diplomatscript
DEFINE VARIABLE a AS CHARACTER NO-UNDO.
DEFINE VARIABLE b AS CHARACTER NO-UNDO.
UPDATE a b.
```

```
r-nextp1.p
```

``` diplomatscript
DEFINE VARIABLE a AS CHARACTER NO-UNDO.
DEFINE VARIABLE b AS CHARACTER NO-UNDO.
NEXT-PROMPT b.
UPDATE a b.
```

**See also** EDITING phrase, Frame phrase

### NEXT-VALUE function

Returns the next INT64 value of a static sequence, incremented by the positive or negative value defined in the Data Dictionary.

**Syntax**

```
NEXT-VALUE ( sequence [ , logical-dbname ] )
```
**sequence**

An identifier that specifies the name of a sequence defined in the Data Dictionary.

**logical-dbname**

An identifier that specifies the logical name of the database in which the sequence is defined. The database must be connected. If multiple databases are connected, you can omit this parameter if you specify a sequence that is unique to one of the databases.

**Example**

The following trigger procedure uses the NextItemNum sequence to set the ItemNum field for a new Item record:

```
TRIGGER PROCEDURE FOR Create OF Item.
/* Automatically assign a unique item number using NextItemNum seq */
ASSIGN Item.ItemNum = NEXT-VALUE(NextItemNum).
```

**Notes**

- If `sequence` is a cycling sequence, and the NEXT-VALUE function increments the sequence beyond its upper limit (for positive increments) or decrements the sequence beyond its lower limit (for negative increments), the function sets and returns the initial value defined for the sequence.

- If `sequence` is a terminating sequence, and the NEXT-VALUE function attempts to increment the sequence beyond its upper limit (for positive increments) or decrement the sequence beyond its lower limit (for negative increments), the function returns the Unknown value (?) and leaves the current sequence value unchanged. Once a sequence terminates, NEXT-VALUE continues to return the Unknown value (?) for the specified sequence until it is reset to a new value with the CURRENT-VALUE statement, or its definition is changed to a cycling sequence. After changing the sequence definition to cycle, the first use of NEXT-VALUE for the sequence sets and returns its initial value.

- The value of a sequence set by the NEXT-VALUE function persists in the database until the next CURRENT-VALUE statement or NEXT-VALUE function is invoked for the sequence, or until the sequence is deleted from the database.

- You cannot invoke the NEXT-VALUE function from within a WHERE clause. Doing so generates a compiler error because the value returned by the NEXT-VALUE function can result in ambiguous expressions. To use a result from the NEXT-VALUE function in a WHERE clause, assign the result to a variable and use the variable in the WHERE clause instead.

- You can use any combination of the NEXT-VALUE function, CURRENT-VALUE function, CURRENT-VALUE statement, and their dynamic versions. Use the dynamic version when you don’t know what the database name or sequence name is at run time.

- Be careful when accessing a database sequence with an alias that points to a different database than the one used when the alias was defined. If you supply an alias name to the CURRENT-VALUE function or the NEXT-VALUE function, only the database used to define the alias is referenced. In this case, it is preferable to use the
NORMALIZE function

Returns the normalized form of a character string based on the specified Unicode normalization form.

**Syntax**

```
NORMALIZE ( string, normalization-form )
```

**string**

The source string to normalize. The value may be of type CHARACTER or LONGCHAR.

If the string is a CHARACTER value, `cpinternal` must be set to UTF-8. If the string is a LONGCHAR value, its code page can be any form of Unicode (for example, UTF-8, UTF-16, or UTF-32). This function returns a value of the same data type as the source string.

**normalization-form**

A character expression that evaluates to one of the following Unicode normalization forms:

- **NFD** — Canonical Decomposition
- **NFC** — Canonical Decomposition, followed by Canonical Composition
- **NFKD** — Compatibility Decomposition
- **NFKC** — Compatibility Decomposition, followed by Canonical Composition
- **NONE** — Returns the source string unchanged

**NOT operator**

Returns TRUE if an expression is false, and FALSE if an expression is true.

**Syntax**

```
NOT expression
```

**expression**

A logical expression whose value is logical, that is TRUE/FALSE, YES/NO.
NOT ENTERED function

Example

In this procedure, if the user enters the number of a Customer that does not exist, the procedure displays a message that the Customer does not exist and the user must try again. If the Customer does exist, the procedure displays the Name and Phone number of the Customer.

r-not.p

```
REPEAT:
PROMPT-FOR Customer.CustNum.
FIND Customer USING Customer.CustNum NO-ERROR.
IF NOT AVAILABLE customer THEN DO:
  MESSAGE "Customer with CustNum:" INPUT Customer.CustNum "does not exist. Please try another.".
  UNDO, RETRY.
END.
ELSE
  DISPLAY Customer.Name Customer.Phone.
END.
```

See also

AND operator, OR operator

NOT ENTERED function

Returns a TRUE value if a frame field was not modified during the last INSERT, PROMPT-FOR, SET, or UPDATE statement.

Note: Does not apply to SpeedScript programming.

Syntax

```
[ FRAME frame ] field NOT ENTERED
```

**FRAME frame**

The frame name that contains the field named by the *field* argument. If you do not name a frame, the NOT ENTERED function starts with the current frame and searches outward until it finds the field you name with the *field* argument.

**field**

The name of the field or variable you are checking.

Example

This procedure displays the CustNum, Name, and CreditLimit for each Customer. For each Customer, the procedure prompts the user for a new CreditLimit value. The NOT ENTERED function tests to see if you enter a value. If you enter a value and it is different from the present value of CreditLimit, the procedure displays the old and new CreditLimit values. If you enter the same value or no value, the procedure displays a message that the CreditLimit has not been changed.
Note

If you use a field or variable referenced with NOT ENTERED in more than one frame, then the AVM uses the value in the frame most recently introduced in the procedure. To make sure you are using the appropriate frame, use the FRAME option with the NOT ENTERED function to reference a particular frame.

See also

ENTERED function

**NOW function**

Returns the current system date, time, and time zone as a DATETIME-TZ value.

The NOW function returns the system date and time of the client or server machine that serves as the time source for applications running during the ABL session (specified by the TIME-SOURCE attribute).

**Syntax**

```
NOW
```

**Example**

Following is an example of using the NOW function:

```
DEFINE VARIABLE v-datetime AS DATETIME NO-UNDO.
DEFINE VARIABLE v-datetime-tz AS DATETIME-TZ NO-UNDO.
ASSIGN
  v-datetime  = NOW
  v-datetime-tz = NOW.
```

NUM-ALIASES function

Returns an INTEGER value that represents the number of aliases defined. The NUM-ALIASES function uses no arguments.

Syntax

```
NUM-ALIASES
```

Example

This procedure displays the number of defined aliases. It also displays the aliases and logical database names of all connected databases.

```
r-numal.p
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DISPLAY NUM-ALIASES LABEL "Number of Defined Aliases:"
REPEAT ix = 1 TO NUM-ALIASES:
  DISPLAY ALIAS(ix) LABEL "Aliases"
  LDBNAME(ALIAS(ix)) LABEL "Logical Database"
END.
```

NUM-DBS function

Takes no arguments; returns the number of connected databases as an INTEGER value.

Syntax

```
NUM-DBS
```

Example

This procedure uses NUM-DBS to display the logical name and database restrictions of all connected databases:

```
r-numdb.p
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
REPEAT ix = 1 TO NUM-DBS:
  DISPLAY LDBNAME(ix) DBRESTRICTIONS(ix) FORMAT "x(40)"
END.
```

See also

ALIAS function, CONNECT statement, CONNECTED function, CREATE ALIAS statement, CREATE CALL statement, DATASERVERS function, DBCODEPAGE function, DBCOLLATION function, DBRESTRICTIONS function, DBTYPE function, DBVERSION function, DELETE ALIAS statement, DISCONNECT statement, FRAME-DB function, LDBNAME function, PDBNAME function, SDBNAME function
NUM-ENTRIES function

Returns the number of elements in a list of character strings as an INTEGER value.

Syntax

```
NUM-ENTRIES ( list [, character ] )
```

**list**

A character expression containing a list of character strings separated with a character delimiter. The list can be a variable of type CHARACTER or LONGCHAR. NUM-ENTRIES returns the number of elements in the list. Specifically, NUM-ENTRIES returns the number of delimiters plus 1, and it returns 0 if `list` equals the empty string ("").

**character**

A delimiter you define for the list. The default is a comma (,). This allows functions to operate on non-comma-separated lists. If you use an alphabetic character, this delimiter is case sensitive.

Examples

This procedure uses NUM-ENTRIES and ENTRY to loop through a list of regions and display them, one per line. Since there are obviously five regions, the REPEAT statement, REPEAT ix = 1 TO 5, works fine here.

```
r-n-ent1.p
```

```
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE regions AS CHARACTER NO-UNDO INITIAL "Northeast,Southest,Midwest,Northwest,Southwest".

REPEAT ix = 1 TO NUM-ENTRIES(regions):
   DISPLAY ENTRY(ix, regions) FORMAT "x(12)".
END.
```

In the following example, PROPATH is a comma-separated list of unknown length:

```
r-n-ent2.p
```

```
DEFINE VARIABLE ix AS INTEGER NO-UNDO.

REPEAT ix = 1 TO NUM-ENTRIES(PROPATH):
   DISPLAY ENTRY(ix, PROPATH) FORMAT "x(64)".
END.
```

This procedure uses NUM-ENTRIES to loop through the PROPATH (a comma-separated list of directory paths) and print the directories, one per line.

This example uses a list that does not use commas as a delimiter. This procedure returns a value of 13:
The NUM-ENTRIES function is multi-byte enabled. The specified list can contain entries that have multi-byte characters and the character delimiter can be a multi-byte character.

See also ENTRY function

**NUM-RESULTS function**

Returns, as an INTEGER value, the number of rows currently in the results list of a scrolling query. The results list is initialized when the query is opened. Depending on the query, the entire list is built immediately upon opening or it is gradually as needed.

**Syntax**

```
NUM-RESULTS ( query-name )
```

**query-name**

A character expression that evaluates to the name of a currently open, scrolling query. If `query-name` does not resolve to the name of a query, or if the query is not open or not scrolling, then the function returns the Unknown value (?).

**Note:** Searching for a query using a handle is more efficient than a character expression. The AVM resolves a character expression at run time by searching in the current routine for a static query with that name. If not found, the AVM searches the enclosing main procedure. If still not found, the AVM searches up through the calling programs of the current routine, and their main procedures. Since a handle uniquely identifies a query, no such search is required. Use the query object handle’s **NUM-RESULTS attribute** to avoid a run-time search.

**Example**

The following example uses the NUM-RESULTS function in a message to report on the number of rows in a browse. Note that the query is opened with the PRESELECT option so that the entire results list is built immediately. Otherwise, NUM-RESULTS might not return the total number of rows in the browse. When you run this procedure and choose a button, the AVM selects certain rows within the browse and then reports on the number of rows selected and the total number of rows in the browse.
DEFINE VARIABLE curr-rec AS ROWID NO-UNDO.
DEFINE VARIABLE status-ok AS LOGICAL NO-UNDO.
DEFINE VARIABLE threshold NO-UNDO LIKE Customer.CreditLimit INITIAL 25000.

NUM-RESULTS function

ON CHOOSE OF no-orders-custs DO:
/* Select those customers with no orders. */
status-ok = brws:DESELECT-ROWS().
HIDE MESSAGE.
FOR EACH Customer NO-LOCK WHERE NOT CAN-FIND(FIRST Order OF Customer):
/* Position query to this record and then select row in browse. */
curr-rec = ROWID(Customer).
REPOSITION qry TO ROWID curr-rec.
status-ok = brws:SELECT-FOCUSED-ROW().
IF NOT status-ok THEN
MESSAGE "Could not select row.".
END.
/* Report number of selected rows and position to first selected. */
MESSAGE brws:NUM-SELECTED-ROWS "of" NUM-RESULTS("qry")
"rows have been selected."
IF brws:NUM-SELECTED-ROWS > 0 THEN
status-ok = brws:SCROLL-TO-SELECTED-ROW(1).
END. /* ON CHOOSE OF no-orders-cust */

ON CHOOSE OF hi-cred-custs DO:
/* Select customers with high credit limits. */
status-ok = brws:DESELECT-ROWS().
HIDE MESSAGE.
/* Get CreditLimit threshold value. */
UPDATE threshold WITH FRAME thresh-frame.
FOR EACH Customer NO-LOCK WHERE Customer.CreditLimit >= threshold:
/* Position query to this record and then select row in browse. */
curr-rec = ROWID(Customer).
REPOSITION qry TO ROWID curr-rec.
status-ok = brws:SELECT-FOCUSED-ROW().
IF NOT status-ok THEN
MESSAGE "Could not select row.".
END. /* ON CHOOSE OF hi-cred-custs */
/* Report number of selected rows and position to first selected. */
MESSAGE brws:NUM-SELECTED-ROWS "of" NUM-RESULTS("qry")
"rows have been selected."
IF brws:NUM-SELECTED-ROWS > 0 THEN
status-ok = brws:SCROLL-TO-SELECTED-ROW(1).
END.

OPEN QUERY qry PRESELECT EACH Customer.
ENABLE ALL WITH FRAME brws-frame.
WAIT-FOR WINDOW-CLOSE OF CURRENT-WINDOW.

Notes

- To use the NUM-RESULTS function with a query, the query must be associated with a browse widget or you must define the query with the SCROLLING option. For more information on query definitions, see the reference entry for the DEFINE QUERY statement.

- If the query is empty, NUM-RESULTS returns 0.

- When possible, the AVM performs optimizations for GET LAST and REPOSITION statements. These optimizations make the results list invalid. At that point,
NUM-RESULTS returns the Unknown value (?). These optimizations do not occur if the query is opened with the PRESELECT option or has an associated browse widget.

**See also** CLOSE QUERY statement, CURRENT-RESULT-ROW function, DEFINE BROWSE statement, DEFINE QUERY statement, GET statement, NUM-RESULTS attribute, OPEN QUERY statement, QUERY-OFF-END function, REPOSITION statement

---

**ON ENDKEY phrase**

Describes the processing that occurs when the ENDKEY condition occurs during a block. This condition usually occurs when the user presses END-ERROR during the first interaction of a block iteration, or any time the user presses a defined END-KEY.

If you use a REPEAT or FOR EACH block, the default processing for ENDKEY is to undo all the processing in the current iteration of the block, then leave the block and continue on to any remaining statements in the routine.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
ON ENDKEY UNDO
   [ label1 ]
   [ , LEAVE [ label2 ]
   | , NEXT [ label2 ]
   | , RETRY [ label1 ]
   | , RETURN [ return-value | ERROR [ return-value | error-object-expression ] ]
   | NO-APPLY ]
```

`label1`

The name of the block whose processing you want to undo. If you do not name a block with `label1`, ON ENDKEY UNDO undoes the processing of the block started by the statement that contains the ON ENDKEY phrase.

`LEAVE [ label2 ]`

Indicates that, after undoing the processing of a block, the AVM leaves the block labeled `label2`. If you do not name a block, the AVM leaves the block containing the ON ENDKEY phrase. After leaving a block, the AVM continues on with any remaining processing in a routine. LEAVE is the default if you do not specify LEAVE, NEXT, RETRY, or RETURN.

`NEXT [ label2 ]`

Indicates that, after undoing the processing of a block, the AVM should execute the next iteration of the block you name with the `label2` option. If you do not name a block with the NEXT option, the AVM executes the next iteration of the block labeled `label1`. 
RETRY [ label1 ]

Indicates that, after undoing the processing of a block, the AVM should repeat the same iteration of the block that you name with the label1 option.

RETRY is the default if you do not specify of LEAVE, NEXT, RETRY, or RETURN.

RETURN ...

Returns to the calling routine, or if there is no calling routine, returns to the OpenEdge Editor. The following table describes various RETURN cases:

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>return-value</td>
<td>The CHARACTER string you provide is passed to the caller. The caller can use the RETURN-VALUE function to read the returned value.</td>
</tr>
<tr>
<td>ERROR</td>
<td>Raises ERROR in the caller and undoes the current subtransaction.</td>
</tr>
</tbody>
</table>
| ERROR return-value      | Raises ERROR in the caller and undoes the current subtransaction. The CHARACTER string you provide is passed to the caller. The caller can use the RETURN-VALUE function to read the returned value.  

The AVM also creates a Progress.Lang.AppError object and stores the return-value in the ReturnValue property.  

**Note:** User-defined functions have different behavior since they must return the data type specified in the definition. See the “FUNCTION statement” section on page 612 for more information. |
| ERROR error-object-expression | Raises ERROR in the caller and undoes the current subtransaction. 

The specified error object is created and populated according to your code. If this is an Progress.Lang.AppError object, the caller can use the RETURN-VALUE function to read the setting of the ReturnValue property. |
| NO-APPLY                | In a user-interface trigger, prevents the AVM from performing the default behavior for that event. |

You cannot specify ERROR within a user-interface trigger block or a destructor. You can specify the NO-APPLY option only within a user-interface trigger block.
ON ERROR phrase

Describes the processing that occurs when there is an error in a block. If you are using a REPEAT block or a FOR EACH block, and an error occurs, all of the processing that has been done in the current iteration of the block is undone, and the AVM retries the block iteration where the error occurred. (If the AVM detects that a RETRY of a FOR or iterating DO block would produce an infinite loop, it performs a NEXT instead. For more information, see OpenEdge Getting Started: ABL Essentials.

Syntax

```abl
ON ERROR UNDO
    [ label1 ]
    [ , LEAVE [ label2 ] ]
    [ , NEXT [ label2 ] ]
    [ , RETRY [ label1 ] ]
    [ , RETURN [ return-value ] ]
    [ , ERROR [ return-value | error-object-expression ] ]
    [ , NO-APPLY ]
    [ , THROW ]
```

`label1`

The name of the block whose processing you want to undo. If you do not name a block with `label1`, ON ERROR UNDO undoes the processing of the block started by the statement that contains the ON ERROR phrase.

`LEAVE [ label2 ]`

Indicates that after undoing the processing of a block, the AVM leaves the block labeled `label2`. If you do not name a block, the AVM leaves the block labeled with `label1`.

Example

In this procedure, if the user presses END-ERROR or END-KEY while changing the CreditLimit field, any changes made during the current iteration of the block are undone, and the same iteration is run again. If this procedure did not use the ON ENDKEY phrase and the user pressed END-ERROR, the procedure ends because the default ENDKEY action is UNDO, LEAVE. After leaving the FOR EACH block, the procedure ends because there are no more statements.

```abl
ON WINDOW-CLOSE OF CURRENT-WINDOW
  STOP.

FOR EACH Customer ON ENDKEY UNDO, RETRY:
  SET Customer.CreditLimit
    VALIDATE(Customer.CreditLimit > 0, "non-zero credit limit").
END.
```

ON ERROR phrase, ON QUIT phrase, ON STOP phrase, RETURN statement, RETURN-VALUE function, UNDO statement
ON ERROR phrase

NEXT [ label2 ]

Indicates that after undoing the processing of a block, the AVM executes the next iteration of the block you name with the label2 option. If you do not name a block with the NEXT option, the AVM executes the next iteration of the block labeled with label1.

RETRY [ label1 ]

Indicates that after undoing the processing of a block, the AVM repeats the same iteration of the block you name with the label1 option.

RETRY is the default processing if you do not use LEAVE, NEXT, RETRY, or RETURN.

RETURN ...

Returns to the calling routine, or if there is no calling routine, returns to the OpenEdge Editor. The following table describes various RETURN cases:

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>return-value</td>
<td>The CHARACTER string you provide is passed to the caller. The caller can use the RETURN-VALUE function to read the returned value.</td>
</tr>
<tr>
<td>ERROR</td>
<td>Raises ERROR in the caller and undoes the current subtransaction.</td>
</tr>
<tr>
<td>ERROR return-value</td>
<td>Raises ERROR in the caller and undoes the current subtransaction. The CHARACTER string you provide is passed to the caller. The caller can use the RETURN-VALUE function to read the returned value. The AVM also creates an Progress.Lang.AppError object and stores the return-value in the ReturnValue property. Note: User-defined functions have different behavior since they must return the data type specified in the definition. See the “FUNCTION statement” section on page 612 for more information.</td>
</tr>
<tr>
<td>ERROR error-object-expression</td>
<td>Raises ERROR in the caller and undoes the current subtransaction. The specified error object is created and populated according to your code. If this is an Progress.Lang.AppError object, the caller can use the RETURN-VALUE function to read the setting of the ReturnValue property.</td>
</tr>
<tr>
<td>NO-APPLY</td>
<td>In a user-interface trigger, prevents the AVM from performing the default behavior for that event.</td>
</tr>
</tbody>
</table>
ON ERROR phrase

You cannot specify ERROR within a user-interface trigger block or a destructor. You can specify the NO-APPLY option only within a user-interface trigger block.

THROW

Use this directive to explicitly propagate an error to the enclosing block.

For example, assume you have an enclosing block with a set of CATCH blocks for handling your error types. Within this block is another block with the ON ERROR UNDO, THROW directive. THROW forces any error in this block to the enclosing block.

If there is a CATCH block within the block with the THROW directive and that CATCH explicitly handles the THROWN error, then the error is not propagated to the enclosing block. In this case, the explicit CATCH block handles the error. The THROW directive only applies to errors that are not explicitly caught.

When used, system error messages generated by statements in the block are suppressed and diverted to a Progress.Lang.SysError object. Any error (SysError, AppError, or user-defined) raised within that block will result in an UNDO of the work in that block’s iteration as long as there is an active transaction. The error object is thrown to the next enclosing block.

Examples

In r-onerr.p, if you enter a Customer number and the FIND statement is unable to find a Customer with that number, the AVM raises an error. If an error occurs, the ON ERROR phrase tells the AVM to undo anything that was done in the current iteration and start the next iteration. Thus, you see any invalid numbers you enter, and you can continue to the next Customer number you want to enter.

```
REPEAT ON ERROR UNDO, NEXT:
  PROMPT-FOR Customer.CustNum.
END.
```

This block propagates an error from a DO block up to the main procedure block. A CATCH block on the main procedure block handles the error.

```
DO ON ERROR UNDO, THROW:
  /* Raises ERROR. The normal error message is diverted to a Progress.Lang.SysError error object and thrown to the main block. */
  FIND Customer 1000.
END. /* DO */

MESSAGE "Undisplayed message because of ERROR condition"
  VIEW-AS ALERT-BOX BUTTONS OK.

/* CATCH for main (procedure) block */
CATCH eAnyError AS Progress.Lang.ERROR:
  MESSAGE "Error message and number retrieved from error object..."
  eAnyError:GetMessage(1) eAnyError:GetMessageNum(1)
  VIEW-AS ALERT-BOX BUTTONS OK.
END CATCH.
```
ON QUIT phrase

Notes

- For callable blocks, including procedures, user-defined functions, class-based methods, and property accessors use the ROUTINE-LEVEL ON ERROR phrase. All of these blocks have a default ON ERROR setting of UNDO, LEAVE.

- ABL handle methods treat errors as warnings and do not raise error, unless the block containing the code uses a CATCH block. To check for handle method errors in blocks without CATCH, use the NO-ERROR option and check ERROR-STATUS: NUM-MESSAGES for a value greater than zero (0). For handle methods, ERROR-STATUS: ERROR is not set.

See also

ON ENDKEY phrase, ON QUIT phrase, ON STOP phrase, RETURN statement, RETURN-VALUE function, ROUTINE-LEVEL ON ERROR UNDO, THROW statement, UNDO statement

ON QUIT phrase

Describes the processing that occurs when a QUIT statement is executed during a block. By default, the QUIT statement saves the current transaction and then returns to the operating system or to the tool from which the routine was invoked (such as the OpenEdge Editor).

Note: Does not apply to SpeedScript programming.

Syntax

```
ON QUIT
  [ UNDO [ label1 ] ]
  [ , LEAVE [ label2 ] ]
  [ , NEXT [ label2 ] ]
  [ , RETRY [ label1 ] ]
  [ , RETURN [ return-value ]
    ERROR [ return-value | error-object-expression ] ]
  | NO-APPLY ]
]```

UNDO [ label1 ]

Indicates that the specified block is undone. If you do not specify the UNDO option, then the current transaction is committed when the QUIT statement is executed.

LEAVE [ label2 ]

Indicates that after committing or undoing the transaction, the AVM leaves the block labeled label1. If you do not name a block, the AVM leaves the block with the ON QUIT phrase in its heading.

NEXT [ label2 ]

Indicates that after committing or undoing the transaction, the AVM executes the next iteration of the block you name with the label option. If you do not name a block with the NEXT option, the AVM executes the next iteration of the block with the ON QUIT phrase in its heading.
RETRY \[ label \]

Indicates that after committing or undoing the processing of a block, the AVM repeats the same iteration of the block that was undone or committed.

RETRY is the default if you do not specify LEAVE, NEXT, RETRY, or RETURN.

RETURN ...

Returns to the calling routine, or if there is no calling routine, returns to the OpenEdge Editor. The following table describes various RETURN cases:

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>return-value</td>
<td>The CHARACTER string you provide is passed to the caller. The caller can use the RETURN-VALUE function to read the returned value.</td>
</tr>
<tr>
<td>ERROR</td>
<td>Raises ERROR in the caller and undoes the current subtransaction.</td>
</tr>
<tr>
<td>ERROR return-value</td>
<td>Raises ERROR in the caller and undoes the current subtransaction. The CHARACTER string you provide is passed to the caller. The caller can use the RETURN-VALUE function to read the returned value. The AVM also creates a Progress.Lang.AppError object and stores the return-value in the ReturnValue property. Note: User-defined functions have different behavior since they must return the data type specified in the definition. See the “FUNCTION statement” section on page 612 for more information.</td>
</tr>
<tr>
<td>ERROR error-object-expression</td>
<td>Raises ERROR in the caller and undoes the current subtransaction. The specified error object is created and populated according to your code. If this is an Progress.Lang.AppError object, the caller can use the RETURN-VALUE function to read the setting of the ReturnValue property.</td>
</tr>
<tr>
<td>NO-APPLY</td>
<td>In a user-interface trigger, prevents the AVM from performing the default behavior for that event.</td>
</tr>
</tbody>
</table>

You cannot specify ERROR within a user-interface trigger block or a destructor. You can specify the NO-APPLY option only within a user-interface trigger block.

See also

ON ENDKEY phrase, ON ERROR phrase, ON STOP phrase, QUIT statement, RETURN statement, RETURN-VALUE function, UNDO statement
ON statement

The ON statement specifies a trigger for one or more events or redefines terminal keys for an application.

Syntax

```
ON event-list
    {    ANYWHERE
        |    {    OF widget-list
                [ OR event-list OF widget-list ] ...
                [ ANYWHERE ]
            }
        }
    {    trigger-block
        |    REVERT
        |    {    PERSISTENT RUN procedure
                [ ( input-parameters ) ]
            }
    }
```

```
ON event OF database-object
    [ referencing_phrase ]
    [ OVERRIDE ]
    {    trigger-block | REVERT }
```

```
ON key-label key-function
```

```
ON "WEB-NOTIFY" ANYWHERE   {    trigger-block }
```

**event-list**

A comma-separated list of user-interface events for which you want to define a trigger. If any of the specified events occurs for any of the specified widgets, the trigger executes.

For a list of valid events for each widget type, see the reference page for that widget type. For information on all user interface events, see the “Handle-based Object Events Reference” section on page 1827.

**widget-list**

A comma-separated list of widgets or procedure handles to which the event is applied. See the Widget phrase reference entry for more information on referencing widgets.

If a specified event occurs for any of the specified widgets, the trigger executes. If you specify a list of widgets, all events specified must be user-interface events.
ANYWHERE

You can specify ANYWHERE either with a list of widgets or instead of a list of widgets. Without a list of widgets, ANYWHERE specifies that the trigger executes when one of the specified events occurs for any widget that does not already have a specific trigger for that event. This lets you define a default trigger for the event within the application. With a list of widgets, ANYWHERE specifies that the trigger executes when one of the specified events occurs for any specified widget or for any contained widget that does not already have a specific trigger for that event. This lets you set up a default trigger for a frame or window.

event

A database event: CREATE, DELETE, FIND, WRITE or ASSIGN. If the specified event occurs for the specified table or field, the trigger executes. For database events, you can specify only one event.

database-object [ referencing-phrase ]

The name of a database table or field to which the event is applied. If you specify a database-object, the event specified must be a database event. You cannot specify a metaschema table or field (a table or field named with an initial underscore) as the database-object.

The referencing-phrase is valid only for WRITE and ASSIGN triggers. For WRITE triggers you can specify a name for the record before the WRITE operation and a name for the record after the WRITE operation. This allows you to reference both versions of the record within the trigger. This is the syntax for WRITE trigger:

Syntax

```
NEW [ BUFFER ] new-record OLD [ BUFFER ] old-record
```

For an ASSIGN trigger, you can specify a name for the old field value. This is the syntax:

Syntax

```
OLD [ VALUE ] old-field-name
```

OVERRIDE

Specifies that the database trigger you are defining overrides the schema trigger for the same event. You can override a schema trigger only if it is defined as overridable in the Data Dictionary. If you do not use the OVERRIDE option, then the session trigger executes first and then the schema trigger.

trigger-block

A trigger block is either a single ABL statement or a set of statements grouped by DO and END statements. The trigger block is executed when one of the specified events is applied to one of the specified widgets or tables.
ON statement

REVERT

If you specify this option, any non-persistent trigger defined in this procedure for the event is reverted. If a trigger had also been defined for the event in a previous procedure, that previous trigger again takes effect. The AVM ignores any attempt to revert a persistent trigger.

PERSISTENT RUN procedure [ ( input-parameters ) ]

Specifies a persistent trigger; that is, a trigger that remains in effect after the current procedure terminates. Normally, a trigger remains in effect only until the procedure or trigger in which it is defined ends. You can specify a persistent trigger only for user-interface events. A persistent trigger must be a procedure specified by `procedure`. The trigger procedure can take one or more input parameters; it cannot have any output parameters. The parameters of the trigger procedure are evaluated when you define the trigger; they are not re-evaluated when the trigger executes.

key-label

The label of the key for which you want to define a specific action. See OpenEdge Development: Programming Interfaces for a list of key labels.

On UNIX, all of the special ABL keys are defined in the PROTERMCAP file supplied with ABL. If the key for which you are defining an action is not already in PROTERMCAP, you must add a definition for that key. Keys that you can name that do not require a PROTERMCAP definition are `CTRL`, `RETURN`, `BACKSPACE`, `TAB`, and `DEL`.

In Windows, keys are predefined as described in the handling user input section of OpenEdge Development: Programming Interfaces.

key-function

The action you want the AVM to take when the user presses the key associated with `key-label`. The `key-function` value can be one of the key functions listed in Table 47.

Table 47: Valid key functions

<table>
<thead>
<tr>
<th>key-function</th>
<th>BACKSPACE</th>
<th>BACK-TAB</th>
<th>BACKSPACE</th>
<th>CURSOR-DOWN</th>
<th>CURSOR-UP</th>
<th>END-ERROR</th>
<th>ENTER-MENUBAR</th>
<th>ERROR</th>
<th>HELP</th>
<th>HOME</th>
<th>LEFT-END</th>
<th>NEXT-FRAME</th>
<th>RECALL</th>
<th>RETURN</th>
<th>SCROLL-MODE</th>
<th>STOP</th>
</tr>
</thead>
<tbody>
<tr>
<td>ABORT</td>
<td>BACKSPACE</td>
<td>BACK-TAB</td>
<td>BACK-TAB</td>
<td>BACK-TAB</td>
<td>BACK-TAB</td>
<td>BACK-TAB</td>
<td>BACK-TAB</td>
<td>END-ERROR</td>
<td>ENTER-MENUBAR</td>
<td>ERROR</td>
<td>LEFT-END</td>
<td>NEXT-FRAME</td>
<td>RECALL</td>
<td>RETURN</td>
<td>SCROLL-MODE</td>
<td>STOP</td>
</tr>
</tbody>
</table>
Examples

The following example defines a WRITE trigger for the customer table:

```
ON WRITE OF Customer NEW new-cust OLD old-cust DO:
   IF new-cust.City <> old-cust.City AND
      new-cust.PostalCode = old-cust.PostalCode THEN DO:
      MESSAGE "Must update postal code, too."
      RETURN ERROR.
   END.
END.
FOR EACH Customer:
   UPDATE Customer.
END.
```

The trigger compares the Customer record before the write with the Customer record after the write. If the city has changed and the postal code has not changed, the trigger displays a message and cancels the write operation.

The following example uses the ON statement to set up a trigger for two buttons:

```
DEFINE BUTTON b_next LABEL "Next".
DEFINE BUTTON b_prev LABEL "Previous".
DEFINE BUTTON b_quit LABEL "Quit".

DEFINE FRAME butt-frame
   b_next b_prev
   WITH CENTERED ROW SCREEN-LINES - 1.
DEFINE FRAME info
   Customer.CustNum Customer.Name
   b_quit AT ROW-OF Customer.CustNum + 2 COLUMN-OF Customer.CustNum + 18
   WITH CENTERED TITLE "Customers" ROW 2 1 COL.

ON CHOOSE OF b_next, b_prev DO:
   IF SELF:LABEL = "Next" THEN
      FIND NEXT Customer NO-LOCK.
   ELSE
      FIND PREV Customer NO-LOCK.
      DISPLAY Customer.CustNum Customer.Name WITH FRAME info.
   END.

ENABLE b_next b_prev WITH FRAME butt-frame.
ENABLE b_quit WITH FRAME info.
WAIT-FOR END-ERROR OF FRAME butt-frame OR
   CHOOSE OF b_quit IN FRAME info FOCUS b_next IN FRAME butt-frame.
```

The following procedure sets up mappings for GO, HELP, and END and defines CTRL+X to ring the terminal bell:

```
ON F1 GO. /* F1 will now perform the GO function */
ON F2 HELP. /* F2 will now perform the HELP function */
ON CTRL-X BELL. /* The Ctrl-X key will be disabled */
ON F5 ENDKEY. /* F5 will always raise the ENDKEY condition; never ERROR*/
```
ON STOP phrase

Notes

- If you use the ON statement to redefine terminal keys, the new definitions remain in effect to the end of the session or until another ON statement changes the definition.

- A trigger defined with the ON statement remains in effect until one of the following occurs:
  - Another ON statement defines another trigger (or REVERT) for the same event and widget
  - For a non-persistent trigger, the procedure or trigger block in which the ON statement appears terminates

- Although each widget type responds with default system actions to a limited set of valid events, you can specify any event for any widget and execute the trigger using the APPLY statement. If the event is not a valid event for the widget type, the specified trigger executes, but no default system action occurs for the widget. You can use this feature to write triggers for procedure handles that do not otherwise respond to events.

- If event-list includes a MENU-DROP event for a menu or submenu, do not interact with the window manager from within the trigger-block. Doing so causes the window manager to lose control of the system, forcing you to reboot or restart the window manager. Actions to avoid include any window system input/output (I/O) or any lengthy processing, especially in statements that cause process interruptions, such as the PAUSE statement with or without I/O. These also include actions that can generate a warning or error message, forcing window system output. Use the NO-ERROR option on supported statements to help avoid this situation. Otherwise, check valid values, especially for run-time resources like handles, to prevent the AVM from displaying unexpected messages.

- For SpeedScript, the only valid uses of the ON statement are specifying a trigger for a database event or for specifying a trigger for a WEB-NOTIFY event (the ON "WEB-NOTIFY" ANYWHERE syntax).

- The ON statement only works with ABL events. You cannot use the ON statement to interact with .NET object events.

See also

APPLY statement, Widget phrase

ON STOP phrase

Describes the processing that occurs when the STOP condition occurs during a block. This condition occurs when a user presses STOP, when a STOP statement is executed, or when certain internal conditions occur within the AVM. The STOP key is usually mapped to CTRL+BREAK (Windows) or CTRL+C (UNIX). By default, the STOP condition undoes active transactions, block by block, until it reaches the outermost block or a block that traps the STOP condition. Control then returns to the Procedure Editor or AppBuilder, if the code was run from that tool.
Almost all STOP conditions are trappable with the ON STOP phrase. In two cases, the AVM may ignore ON STOP phrases. First, if the AVM executes a procedure that relies on a lost database connection, the AVM raises the STOP condition and unwinds the call stack until it gets to a level above all references to the lost database. If it encounters an ON STOP before this point it ignores it. If it encounters an ON STOP phrase after this point, then the AVM executes the ON STOP. Similarly, if the AVM encounters an I/O blocking statement inside a user-defined function or a non-void method, the STOP condition is raised, and the AVM unwinds the procedure stack ignoring ON STOP phrases until it gets to a point above the user-defined function or non-void method call.

Syntax

```
ON STOP UNDO
  [  label1  ]
  [         , LEAVE [  label2  ]
          | , NEXT [  label2  ]
          | , RETRY [  label1  ]
          | , RETURN [  return-value  
                        ERROR [  return-value  | error-object-expression ] |
                        NO-APPLY ]
  ]
```

`label1`

The name of the block whose processing you want to undo. If you do not name a block with `label1`, ON STOP UNDO undoes the processing of the block started by the statement that contains the ON STOP phrase.

`LEAVE [  label2  ]`

Indicates that after undoing the processing of a block, the AVM leaves the block labeled `label2`. If you do not name a block, the AVM leaves the block labeled with `label1`.

`NEXT [  label2 ]`

Indicates that after undoing the processing of a block, the AVM executes the next iteration of the block you name with the `label2` option. If you do not name a block with the NEXT option, the AVM executes the next iteration of the block labeled with `label1`.

`RETRY [  label1 ]`

Indicates that after undoing the processing of a block, the AVM repeats the same iteration of the block you name with the `label1` option.

RETRY is the default processing if you do not use LEAVE, NEXT, RETRY, or RETURN.

`RETURN ...`

Returns to the calling routine, or if there is no calling routine, returns to the OpenEdge Editor. The following table describes various RETURN cases:
ON STOP phrase

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>return-value</code></td>
<td>The CHARACTER string you provide is passed to the caller. The caller can use the RETURN-VALUE function to read the returned value.</td>
</tr>
<tr>
<td>ERROR</td>
<td>Raises ERROR in the caller and undoes the current subtransaction.</td>
</tr>
<tr>
<td>ERROR <code>return-value</code></td>
<td>Raises ERROR in the caller and undoes the current subtransaction. The CHARACTER string you provide is passed to the caller. The caller can use the RETURN-VALUE function to read the returned value.</td>
</tr>
<tr>
<td></td>
<td>The AVM also creates an Progress.Lang.AppError object and stores the <code>return-value</code> in the ReturnValue property.</td>
</tr>
<tr>
<td>Note:</td>
<td>User-defined functions have different behavior since they must return the data type specified in the definition.</td>
</tr>
<tr>
<td></td>
<td>See the “FUNCTION statement” section on page 612 for more information.</td>
</tr>
<tr>
<td>ERROR <code>error-object-expression</code></td>
<td>Raises ERROR in the caller and undoes the current subtransaction. The specified error object is created and populated according to your code.</td>
</tr>
<tr>
<td></td>
<td>If this is an Progress.Lang.AppError object, the caller can use the RETURN-VALUE function to read the setting of the ReturnValue property.</td>
</tr>
<tr>
<td>NO-APPLY</td>
<td>In a user-interface trigger, prevents the AVM from performing the default behavior for that event.</td>
</tr>
</tbody>
</table>

You cannot specify ERROR within a user-interface trigger block or a destructor. You can specify the NO-APPLY option only within a user-interface trigger block.

This procedure lets you update the CreditLimit field for each Customer. If you enter a value greater than 100,000, the program raises the STOP condition. Since you specified an UNDO, RETRY for a STOP, the procedure starts the iteration over and allows you to enter another value.

`r-ostop.p`

```
FOR EACH Customer ON STOP UNDO, RETRY:
  UPDATE Customer.CreditLimit.
  IF Customer.CreditLimit > 100000 THEN STOP.
END.
```
ON STOP phrase

The ON STOP phrase is especially useful to trap the STOP condition that results when a user cancels out of a record lock conflict in an application. The r-ostop2.p procedure is a simple record navigation and update utility that finds Salesrep records with the SHARE-LOCK condition. The user can update the values of a Salesrep record in the frame and choose the Assign button to assign the new values to the database. If the user attempts to update a Salesrep record that another user already has in the SHARE-LOCK condition, the r-ostop2.p procedure freezes as a result of the record locking conflict. The AVM displays a message asking the user to wait for the other user to relinquish the lock on the record or to press the STOP key to abort the operation.

By default, the STOP key aborts the procedure. The ON STOP phrase on the DO TRANSACTION block in the r-ostop2.p procedure captures the STOP condition and returns control to the procedure.

r-ostop2.p

```plaintext
DEFINE VARIABLE methRtn AS LOGICAL NO-UNDO.
DEFINE BUTTON buta LABEL "Find Next".
DEFINE BUTTON butb LABEL "Assign".
DEFINE BUTTON butc LABEL "Done".

DEFINE FRAME a
Salesrep.SalesRep SKIP Salesrep.RepName SKIP Salesrep.Region SKIP
buta butb Butc
WITH 1 DOWN NO-BOX SIDE-LABELS.

/*******TRIGGERS******/
ON CHOOSE OF buta DO:
FIND NEXT SalesRep SHARE-LOCK.
IF NOT AVAILABLE SalesRep THEN
MESSAGE "No Next SalesRep".
DISPLAY SalesRep WITH FRAME a.
END.

ON CHOOSE OF butb DO:
DO TRANSACTION ON STOP UNDO, LEAVE:
END.

ON CHOOSE OF butc DO:
  APPLY "ENDKEY" TO FRAME a.
END.

/*******MAIN BLOCK******/
FIND FIRST SalesRep SHARE-LOCK.
DISPLAY SalesRep WITH FRAME a.

ENABLE ALL WITH FRAME a.
WAIT-FOR ENDKEY OF FRAME a a FOCUS buta.
```

See also ON ENDKEY phrase, ON ERROR phrase, ON QUIT phrase, RETURN statement, RETURN-VALUE function, STOP statement
OPEN QUERY statement

Opens a query, which might have been previously defined in a DEFINE QUERY statement. Opening a query makes it available for use within a GET statement, or in a browse widget.

Syntax

```
OPEN QUERY query { FOR | PRESELECT } EACH record-phrase
[ , { EACH | FIRST | LAST } record-phrase ] ... 
[ query-tuning-phrase ]
[ BREAK ]
[ BY expression [ DESCENDING ]
  | COLLATE ( string, strength [ , collation ] ) [ DESCENDING ]
] ... 
[ INDEXED-REPOSITION ]
[ MAX-ROWS num-results ]
```

query

The query to open. The query name may have been defined previously in a DEFINE QUERY statement. Otherwise, the OPEN QUERY statement implicitly defines the query.

{ FOR | PRESELECT } EACH record-phrase

Specifies the first buffer of the query.

The following is the syntax for record-phrase:

Syntax

```
record
[ [ LEFT ] ] [ OF table ]
[ WHERE expression ]
[ USING [ FRAME frame ] field
  [ AND [ FRAME frame ] field ] ... ]
[ USE-INDEX index ]
[ SHARE-LOCK | EXCLUSIVE-LOCK | NO-LOCK ]
[ NO-PREFETCH ]
```

If the query was previously defined, the buffers referenced by the record-phrase must be the same buffers referenced in the DEFINE QUERY statement and in the same order. For more information, see the Record phrase reference entry.

Note that the first buffer must be qualified with EACH rather than the FIRST option. That is, the OPEN QUERY statement implies the possibility of a multi-row result, whether or not only one row is returned.

If you specify PRESELECT rather than FOR, then the AVM preselects the records for the query. During the preselect process, the AVM applies whatever locking is specified in the OPEN QUERY statement or, if none is specified, SHARE-LOCK. It then reads the ROWID for each record into the result list. (If you do not specify PRESELECT, the AVM
might pass through the records anyway to presort them. In this case, the AVM applies NO-LOCK to each record during this pass.)

\[ \{ \text{EACH} | \text{FIRST} | \text{LAST} \} \text{ record-phrase} \]

Specifies subsequent buffers in the query. Each subsequent buffer specifies a join with the previous buffer(s) according to the record-phrase. If the query was previously defined, the buffers referenced by the record-phrase must be the same buffers referenced in the DEFINE QUERY statement and in the same order. For more information on specifying joins in Record phrases, see the Record phrase reference entry.

**query-tuning-phrase**

Allows programmatic control over the execution of a DataServer query. Following is the syntax for the query-tuning-phrase:

**Syntax**

```verbatim
QUERY-TUNING ( 
  [ LOOKAHEAD [ CACHE-SIZE integer ] ] | NO-LOOKAHEAD ]
  [ DEBUG { SQL | EXTENDED } ] | NO-DDEBUG ]
  [ SEPARATE-CONNECTION | NO-SEPARATE-CONNECTION ]
  [ JOIN-BY-SQLDB | NO-JOIN-BY-SQLDB ]
  [ BIND-WHERE | NO-BIND-WHERE ]
  [ INDEX-HINT | NO-INDEX-HINT ]
)
```

For more information, see your OpenEdge DataServer Guides (*OpenEdge Data Management: DataServer for Microsoft SQL Server*, *OpenEdge Data Management: DataServer for ODBC*, and *OpenEdge Data Management: DataServer for Oracle*).

**BREAK**

Over a series of query iterations, you might want to do some work based on whether the value of a certain field changes. This field defines a break group. For example, you might be accumulating some value, such as a total. You use the BREAK option to define customer.state as the break group, as shown:

```verbatim
OPEN QUERY q-order FOR EACH customer BREAK BY customer.state NO-LOCK.
```

When using the BREAK option you must also use the BY option to name a sort field.

To test whether a break group has changed, you can use the FIRST-OF( ) method and LAST-OF( ) method of the query object handle.

**BY expression [ DESCENDING ]**

Specifies the order in which records are to be returned. If an index is defined with the right leading keys to satisfy the BY clause, the AVM uses that index to sort the records. Otherwise, the AVM must presort the records before the first fetch when you specify BY. The DESCENDING option sorts the records in descending order (not in the default ascending order).
OPEN QUERY statement

COLLATE ( string , strength [ , collation ] ) [ DESCENDING ]

Generates the collation value of a string after applying a particular strength, and optionally, a particular collation. The DESCENDING option sorts the records in descending order (not in default ascending order).

**string**

A CHARACTER expression that evaluates to the string whose collation value you want to generate.

**strength**

A CHARACTER expression that evaluates to an ABL comparison strength or an International Components for Unicode (ICU) comparison strength.

The ABL comparison strengths include:

- **RAW** — Generates a collation value for the string based on its binary value.
- **CASE-SENSITIVE** — Generates a case-sensitive collation value for the string based on a particular collation. If you specify this strength with an ICU collation, the AVM applies the ICU TERTIARY strength.
- **CASE-INSENSITIVE** — Generates a case-insensitive collation value for the string based on a particular collation. If you specify this strength with an ICU collation, the AVM applies the ICU SECONDARY strength.
- **CAPS** — Generates a collation value for the string based on its binary value after converting any lowercase letters in the string to uppercase letters, based on the settings of the Internal Code Page (-cpinternal) and Case Table (-cpcase) startup parameters.

The ICU comparison strengths include:

- **PRIMARY** — Generates a collation value for the base characters in the string.
- **SECONDARY** — Generates a collation value for the base characters and any diacritical marks in the string.
- **TERTIARY** — Generates a case-sensitive collation value for the base characters and any diacritical marks in the string.
- **QUATERNARY** — Generates a case-sensitive collation value for the base characters and any diacritical marks in the string, and distinguishes words with and without punctuation. ICU uses this strength to distinguish between Hiragana and Katakana when applied with the ICU-JA (Japanese) collation. Otherwise, it is the same as TERTIARY.

**Note:** Use ICU comparison strengths only with ICU collations.
**collation**

A CHARACTER expression that evaluates to the name of an ABL collation table or ICU collation. If `collation` does not appear, COLLATE uses the collation table of the client.

The AVM reports an error and stops execution if one of the following occurs:

- `strength` does not evaluate to a valid value.
- `collation` does not evaluate to a collation table residing in the `convmap.cp` file.
- `collation` evaluates to a collation table that is not defined for the code page corresponding to the `-cpinternal` startup parameter.

**INDEXED-REPOSITION**

If you specify this option, the AVM attempts to optimize subsequent REPOSITION TO ROWID operations on the query. This can improve the performance of REPOSITION operations that must jump over many records in a simple query. Optimization is not possible if the database is not an OpenEdge database, or sorting or preselection is performed. In these cases, the INDEXED-REPOSITION option is ignored and no error is reported.

The optimization has some side effects. When you perform a REPOSITION TO ROWID with this optimization, the AVM discards the original result list and begins a new one. Therefore, scrolling forward or backward in the list might return different records from before. Also, the values of the NUM-RESULTS and CURRENT-RESULT-ROW become invalid. If the query has an associated browse, any selections in that browse are also lost. Lastly, the vertical scrollbar thumb is disabled. Because of these side-effects, use this option selectively.

**MAX-ROWS num-results**

Specifies the maximum number of records to be returned by the query. Any other records satisfying the query are ignored and no error is raised. The limit is imposed before any sorting occurs; the AVM retrieves records up to the number specified and then sorts those records.

This option is valid for scrolling queries only. You can use it to prevent a long delay that might occur if a query returns many more records than you expect.

**Example**

The following example opens a query on the Customer, Order, OrderLine, and Item tables:
Note the use of field lists in the DEFINE QUERY statement. This can improve the performance of remote database queries significantly.

**Notes**

- If the query you reference in an OPEN QUERY statement is already open, then that query is closed and a new query is opened.

- If you use the USE-INDEX option of the Record phrase, the AVM uses only that index. Records are returned in index order.

- The locking options of the OPEN QUERY statement define the default locking for records fetched by the query. You can override the default by using a locking option in the GET statement. Note, however, that in the OPEN QUERY statement you can specify a separate lock type for each buffer; in the GET statement you can specify only one lock type that applies to all buffers in a join.

- The record locking behavior specified for a query in the DEFINE BROWSE statement overrides the record locking behavior specified with the OPEN QUERY statement. The default record locking behavior of a browse widget is NO-LOCK. The default record locking behavior of a query defined with the OPEN QUERY statement is SHARE-LOCK. If you define a query and a browse widget for the query without explicitly defining record locking behavior, the query will have the NO-LOCK behavior.

- Each time you open a query associated with a browse widget, the data in the browse is refreshed.

- If you reopen a query to refresh the data displayed in a browse widget, a selected row might not reflect the database’s most current data. To view the latest data in a selected row, add a FIND CURRENT statement before the OPEN QUERY statement. This additional
code allows the AVM to put the current record into memory before executing the OPEN QUERY statement.

- You cannot use the CAN-FIND function in a WHERE clause. Doing so generates a compiler error.

- If you open a query that has already been defined with multiple buffers, you must specify the buffers in the same order in the OPEN QUERY as they were specified in the DEFINE QUERY statement.

- Once the query has been opened, you cannot change the buffers that it references, even if the query is closed and re-opened. For example, a buffer, buff1, is created for the customer table in a DEFINE QUERY or OPEN QUERY for the query, qry1. The query is run and closed. You cannot now DEFINE or OPEN qry1 with buff1 for the item table. You can reuse buffers with CREATE QUERY, but you must re-run QUERY-PREPARE.

- A ProDataSet data-relation defined with REPOSITION or SELECTION is overridden if a query is defined for a child relation data-source. Normally, if REPOSITION is not specified, the child query selects the children of the parent. But coding a query for the child data-source overrides whether or not a SELECTION or REPOSITION relation mode was defined.

See also CLOSE QUERY statement, CREATE QUERY statement, CURRENT-RESULT-ROW function, DEFINE BROWSE statement, DEFINE DATASET statement, DEFINE QUERY statement, GET statement, NUM-RESULTS function, QUERY-OFF-END function, QUERY-PREPARE( ) method, REPOSITION statement

OPSYS function

Identifies the operating system being used, so that a single version of a procedure can work differently under different operating systems. Returns the value of that operating system. Valid values are “UNIX” and “WIN32”.

Syntax

OPSYS

Example

This procedure produces a listing of the files in your current directory. The OPSYS function determines which operating system you are running, and uses the appropriate operating system command to produce the directory listing. The example shows the possible return values.

r-opsys.p

IF OPSYS = "UNIX" THEN UNIX ls.
ELSE IF OPSYS = "WIN32" THEN DOS dir.
ELSE MESSAGE OPSYS “is an unsupported operating system”.

OPSYS function
ABL supports an override option that enables applications that need to return the value of MS-DOS for all Microsoft operating systems to do so. For example, if you do not want the value WIN32 returned when either Windows 95 or Windows NT operating systems are recognized, you can override this return value by defining the Opsys key in the Startup section of the current environment, which may be in the registry or in an initialization file. If the Opsys key is located, the OPSYS function returns the value associated with the Opsys key on all platforms.

See also
DOS statement, UNIX statement, { } Preprocessor name reference

---

### OR operator

Returns a TRUE value if either of two logical expressions is TRUE.

**Syntax**

```
expression OR expression
```

**expression**

A logical expression (a constant, field name, variable name or expression whose value is logical, that is, TRUE/FALSE, YES/NO).

**Example**

This procedure lists Customers who have no postal code (`PostalCode = ""`) or that have no telephone number (`Phone = ""`), and displays how many Customers are in the list:

```
r-or.p
FOR EACH Customer NO-LOCK
WHERE Customer.PostalCode = "" OR Customer.Phone = "":
END.
```

See also
AND operator, NOT operator

---

### OS-APPEND statement

Executes an operating system file append command from within ABL.

**Syntax**

```
OS-APPEND
{ source-filename | VALUE ( expression ) }
{ target-filename | VALUE ( expression ) }
```

**source-filename**

The name of the source file. (If you append file A to file B, file A is the source file.) If you specify a directory, OS-APPEND generates an error.
OS-APPEND statement

VALUE ( expression )

An expression that returns the name of the source file. (If you append file A to file B, file A is the source file.) expression can contain constants, field names, and variable names.

target-filename

The name of the target file. (If you append file A to file B, file B is the target file.)

VALUE ( expression )

An expression that returns the name of the target file. (If you append file A to file B, file B is the target file.) expression can contain constants, field names, and variable names.

Example

This procedure opens a dialog box that prompts the user to choose a source file for the append. It then prompts for a name for the target file. Finally, the procedure uses the OS-APPEND statement to append the source file to the target file.

r-os-app.p

```
DEFINE VARIABLE sourcefile AS CHARACTER NO-UNDO.
DEFINE VARIABLE targetfile AS CHARACTER NO-UNDO FORMAT "x(20)"
    VIEW-AS FILL-IN.
DEFINE VARIABLE OKpressed AS LOGICAL NO-UNDO INITIAL TRUE.

Main:
REPEAT:
    SYSTEM-DIALOG GET-FILE sourcefile
        TITLE "Choose Source File For Append"
        MUST-EXIST
        USE-FIILENAME
        UPDATE OKpressed.

    IF OKpressed = FALSE THEN
        LEAVE Main.
    UPDATE targetfile WITH FRAME appendframe.
    OS-APPEND VALUE(sourcefile) VALUE(targetfile).
END.
```

Notes

- The filenames must conform to the naming conventions of the underlying operating system.

- If target-file names a file that does not exist or a directory, OS-APPEND becomes an OS-COPY and a copy is created in the current or specified directory. If an error occurs during the copy, the AVM deletes the partial target-file.

- Although an error can occur during execution of this statement, the statement does not generate an error message, raise an error condition, or affect the program’s flow in any way. Check for an execution error by using the OS-ERROR function and evaluating the return.

- If you specify the same file for the source and the target, the append fails but OS-ERROR is not set.

See also

OS-ERROR function
OS-COMMAND statement

Escapes to the current operating system and executes an operating system command.

Syntax

```
OS-COMMAND
  [ SILENT | NO-WAIT | NO-CONSOLE ]
  [ command-token | VALUE ( expression ) ] ... 
```

SILENT

After processing an operating system command, the AVM shell pauses. To exit the window in Windows GUI platforms, you must type `exit`. To exit the window in Windows character platforms, you must type `exit` and press RETURN or SPACEBAR. You can use the SILENT option to eliminate this pause. Use this option only if you are sure that the program, command, or batch file does not generate any output to the screen. Cannot be used with NO-WAIT.

NO-WAIT

In a multi-tasking environment, causes the AVM to immediately pass control back to next statement after the OS-COMMAND without waiting for the operating system command to terminate. Cannot be used with SILENT. This option is supported in Windows only.

NO-CONSOLE

While processing an operating system command, the AVM creates a console window. The console window may not be cleaned up after the command is executed. You can use the NO-CONSOLE option to prevent this window from being created in the first place.

```
command-token | VALUE ( expression )
```

One or more command words and symbols that you want to pass the operating system to execute. The VALUE option generates the command tokens included in `expression`, a character string expression. The specified combination of `command-token` and `VALUE(expression)` options can form any legal combination of commands and command options permitted by the operating system.

Example

There are two principal uses for the OS-COMMAND statement: to execute a utility that has the same syntax on two or more different operating systems, and to execute an operating system statement input by a user.

In both instances, the OS-COMMAND statement eliminates the need to use the OPSYS statement to determine the operating system and then use conditional logic to execute the appropriate code. The OS-COMMAND statement, therefore, makes an application more portable.

This procedure prompts the user for an operating system command and then uses the OS-COMMAND statement to execute the command:
r-os-com.p

```abl
DEFINE VARIABLE comm-line AS CHARACTER NO-UNDO FORMAT "x(70)".
REPEAT:
  UPDATE comm-line.
  OS-COMMAND VALUE(comm-line).
END.
```

**Notes**

- If you want to run an operating system internal command, such as Windows `dir`, do not use the NO-WAIT keyword. The results are unpredictable.
- If you want to run an application that requires Windows, you must use the NO-WAIT option.
- The NO-WAIT option is unavailable in environments that are not multi-tasking.
- The OS-COMMAND statement always sets the value for the OS-ERROR function to 0, whether or not an error occurs. Thus, an operating system error is never returned for the OS-COMMAND statement.

**See also**

DOS statement, OPSYS function, OS-ERROR function, UNIX statement

---

**OS-COPY statement**

Executes an operating system file copy command from within ABL.

**Syntax**

```
OS-COPY
{ source-filename | VALUE ( expression ) }
{ target-filename | VALUE ( expression ) }
```

- **source-filename**
  
  The name of the original file. If you specify a directory, OS-COPY generates an error.

  `VALUE ( expression )`

  An expression that returns the name of the original file. *Expression* can contain constants, field names, and variable names.

- **target-filename**

  The name of the new file or directory. If you specify a directory, OS-COPY gives the target file the same name as the source file.

  `VALUE ( expression )`

  An expression that returns the name of the new file or directory. *expression* can contain constants, field names, and variable names.

**Example**

This procedure opens a dialog box that prompts the user to choose a file to copy. It then prompts for a name for the copy. Finally, the procedure uses the OS-COPY statement to copy the file.
The filenames must conform to the naming conventions of the underlying operating system.

- If target-file specifies an existing file, OS-COPY overwrites the existing file.
- If target-file has the same name as source-file, the copy fails, but OS-ERROR is not set.
- If the copy terminates abnormally, the AVM deletes the partial target-file.
- Enclose filenames that refer to physical devices in double quotes (" ").
- Although an error can occur during execution of this statement, the statement does not generate an error message, raise an error condition, or affect the program’s flow in any way. Check for an execution error by using the OS-ERROR function and evaluating the return.

OS-ERROR function

OS-CREATE-DIR statement

Executes an operating system command from within ABL that creates one or more new directories.

Syntax

```
OS-CREATE-DIR { dirname | VALUE ( expression ) } ...
```

dirname

The name of a directory to create. If the directory already exists, no error is generated. If a file with this name exists, an error is generated. The name can be a pathname or a simple name.
If *dirname* is not a fully qualified directory name, ABL prepends the current working directory to *dirname*.

**VALUE (expression)**

An expression that returns the name of a directory to create. *Expression* can contain constants, field names, and variable names.

**Example**

The following procedure prompts the user for the name of a directory, then creates it. If the name you give is not fully qualified, the directory is created in your current directory.

```plaintext
DEFINE VARIABLE stat AS INTEGER NO-UNDO.
DEFINE VARIABLE dir_name AS CHARACTER NO-UNDO FORMAT "x(64)"
   LABEL "Enter the name of the directory you want to create."
   UPDATE dir_name.
   OS-CREATE-DIR VALUE(dir_name).
   stat = OS-ERROR.
   IF stat NE 0 THEN
      MESSAGE "Directory not created. System Error #" stat.
```

**Notes**

- The directory name must conform to the naming conventions of the underlying operating system.
- If a specified directory cannot be created, ABL returns an error code.
- Although an error can occur during execution of this statement, the statement does not generate an error message, raise an error condition, or affect the program’s flow in any way. Check for an execution error by using the OS-ERROR function and evaluating the return.

**See also**

- OS-ERROR function

---

**OS-DELETE statement**

Executes an operating system file or directory delete from within ABL. Can delete one or more files, a directory, or an entire directory branch.

**Syntax**

```plaintext
OS-DELETE
   \{ filename | VALUE ( expression ) \} ... [ RECURSIVE ]
```

*filename*

The name of the files or directories to delete. If you specify a directory that is not empty, you must also specify the RECURSIVE option to delete both the files contained within the directory and the directory itself.
VALUE ( expression )

An expression that returns the name of the files or directories to delete. expression can contain constants, field names, and variable names.

RECURSIVE

Instructs OS-DELETE to delete all subdirectories of the directory named in filename, as well as the directory itself. Before a directory or subdirectory is deleted, its files are deleted.

Example

This procedure opens a dialog box that prompts the user to choose a file to delete, then uses the OS-DELETE statement to delete the file:

r-os-del.p

```
DEFINE VARIABLE filename AS CHARACTER NO-UNDO.
DEFINE VARIABLE OKpressed AS LOGICAL NO-UNDO INITIAL TRUE.

Main:
REPEAT:
    SYSTEM-DIALOG GET-FILE filename
    TITLE "Choose File to Delete"
    MUST-EXIST
    USE-FILENAME
    UPDATE OKpressed.
    IF OKpressed = FALSE THEN LEAVE Main.
    ELSE OS-DELETE VALUE(filename).
END.
```

Notes

- The filenames and directory names must conform to the naming conventions of the underlying operating system.
- If OS-DELETE encounters files or directories that are protected against deletes, it skips over them, generates an error code, but continues to delete any unprotected files and subdirectories that are specified. If several such files or directories are encountered, OS-ERROR returns information on the last error only. If a subdirectory cannot be deleted, then the named directory is not deleted.
- You cannot use wildcard characters to specify files or directories.
- Although an error can occur during execution of this statement, the statement does not generate an error message, raise an error condition, or affect the program’s flow in any way. Check for an execution error by using the OS-ERROR function and evaluating the return.

See also

OS-ERROR function

OS-DRIVES function

(Windows only)

Returns a comma-separated list of available drives.
OS-ERROR function

Returns, as an INTEGER value, an ABL error code that indicates whether an execution error occurred during the last OS-APPEND, OS-COPY, OS-CREATE-DIR, OS-DELETE, OS-RENAME or SAVE CACHE statement.

Syntax

OS-ERROR

Example

The following procedure prompts the user to enter a file to delete, attempts to delete the file, and then calls the OS-ERROR function to check for an execution error. If an error occurs, the procedure branches based on the error number and responds accordingly.

r-os-err.p

```abl
DEFINE VARIABLE err-status AS INTEGER NO-UNDO.
DEFINE VARIABLE filename AS CHARACTER NO-UNDO FORMAT "x(40)"
   LABEL "Enter a file to delete".

UPDATE filename.
OS-DELETE VALUE(filename).
err-status = OS-ERROR.

IF err-status <> 0 THEN
   CASE err-status:
      WHEN 1 THEN
         MESSAGE "You are not the owner of this file or directory.".
      WHEN 2 THEN
         MESSAGE "The file or directory you want to delete does not exist.".
      OTHERWISE
         DISPLAY "OS Error #" + STRING(OS-ERROR,"99") FORMAT "x(13)"
            WITH FRAME b.
   END CASE.
```

Note

On platforms other than Windows, OS-DRIVES compiles and executes, but returns the empty string (""").

OS-DRIVES

The following procedure populates a selection list with the output of the OS-DRIVES function, and then displays the list and prompts the user to select a drive. The procedure then informs the user that subsequent writes will be to the selected drive.

r-os-drv.p

```abl
DEFINE VARIABLE drives AS CHARACTER NO-UNDO LABEL "Select a Drive"
   VIEW-AS SELECTION-LIST INNER-CHARS 3 INNER-LINES 5.

DEFINE FRAME f
   drives.

drives:LIST-ITEMS = OS-DRIVES.
UPDATE drives WITH FRAME f.
MESSAGE "Files will be written to drive" INPUT drives:SCREEN-VALUE.
```
OS-ERROR function

Notes

- This function returns 0 if no error occurred.
- Use this function immediately following an OS-APPEND, OS-COPY, OS-CREATE-DIR, OS-DELETE, OS-RENAME, or SAVE CACHE statement to determine whether an error occurred during the statement’s execution. If you do not, the next use of one of these statements overwrites the previous error code.
- Table 48 lists the ABL error codes that the OS-ERROR function can return.

Table 48: ABL OS-ERROR codes

<table>
<thead>
<tr>
<th>Error number</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>No error</td>
</tr>
<tr>

See also OS-APPEND statement, OS-COPY statement, OS-CREATE-DIR statement, OS-DELETE statement, OS-RENAME statement, SAVE CACHE statement
**OS-GETENV function**

Returns a string that contains the value of the desired environment variable in the environment in which the ABL session is running.

**Syntax**

```
OS-GETENV ( environment-variable )
```

*environment-variable*

The name of the environment variable whose value you want to find.

**Example**

This procedure prompts a user for a report name. It then builds the full pathname where the report will be stored, using OS-GETENV to find the DLC directory. Finally, the procedure displays the full pathname.

```
r-os-env.p
```

```apl
DEFINE VARIABLE pathname AS CHARACTER NO-UNDO FORMAT "x(32)"
LABEL "The report will be stored in ".
DEFINE VARIABLE report_name AS CHARACTER NO-UNDO FORMAT "x(32)"
LABEL "Please enter report name."
UPDATE report_name.
pathname = OS-GETENV("DLC") + "/" + report_name.
DISPLAY pathname WITH FRAME b SIDE-LABELS.
```

**Notes**

- If the environment variable is not defined, this statement returns the Unknown value (?).
- This function returns the value of an environment variable defined before the ABL session started, not a variable defined during the session.
- Since environment variables are case sensitive in some environments, make sure that the name you supply is the correct case.

**OS-RENAME statement**

Executes an operating system file rename or directory rename command from within ABL.

**Syntax**

```
OS-RENAME
{ source-filename | VALUE ( expression ) }
{ target-filename | VALUE ( expression ) }
```

*source-filename*

The name of the file or directory to rename.

*VALUE ( expression )*

An expression that returns the name of the file or directory to rename. *expression* can contain constants, field names, and variable names.
target-filename

The new name of the file or directory.

VALUE ( expression )

An expression that returns the new name of the file or directory. expression can contain
constants, field names, and variable names.

**Example**

This procedure opens a dialog box that prompts the user to choose a file to rename. It then
prompts for a new name. Finally, the procedure uses the OS-RENAME statement to rename the
file.

```r-os-nam.p
DEFINE VARIABLE sourcefile AS CHARACTER NO-UNDO.
DEFINE VARIABLE targetfile AS CHARACTER NO-UNDO FORMAT "x(20)"
   VIEW-AS FILL-IN.
DEFINE VARIABLE OKpressed AS LOGICAL NO-UNDO INITIAL TRUE.

Main:
REPEAT:
   SYSTEM-DIALOG GET-FILE sourcefile
      TITLE "Choose a File or Directory to Rename"
      MUST-EXIST
      USE-FILENAME
      UPDATE OKpressed.
      IF OKpressed = FALSE THEN
         LEAVE Main.
      END.
   UPDATE targetfile WITH FRAME newnameframe.
   OS-RENAME VALUE(sourcefile) VALUE(targetfile).
END.
```

**Notes**

- The filenames or directory names must conform to the naming conventions of the
  underlying operating system.
- If source-filename and target-filename specify different directories, this statement
  both renames the file and moves it to the new directory.
- Although an error can occur during execution of this statement, the statement does not
generate an error message, raise an error condition, or affect the program’s flow in any
way. Check for an execution error by using the OS-ERROR function and evaluating the
return.

**See also**  OS-ERROR function

**OUTPUT CLOSE statement**

Closes the default output destination or the output stream you name with the STREAM keyword
in a prior OUTPUT TO statement.

**Syntax**

```
OUTPUT [ STREAM stream | STREAM-HANDLE handle ] CLOSE
```
STREAM stream

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream. See the DEFINE STREAM statement reference entry and the chapter on alternate I/O sources in *OpenEdge Development: Programming Interfaces* for more information on streams.

STREAM-HANDLE handle

Specifies the handle to a stream. If handle it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in *OpenEdge Development: Programming Interfaces* for more information on streams and stream handles.

Example

This procedure sends Customer data to a file by using the OUTPUT TO statement. All statements that normally send output to the terminal send output to the file named cust.dat. After all Customer data is written to the file, the OUTPUT CLOSE statement resets the output destination, usually the terminal. The final DISPLAY statement displays "Finished" on the terminal.

```
r-out.p

OUTPUT TO cust.dat.

FOR EACH Customer NO-LOCK:
        Customer.City Customer.State Customer.Country SKIP(2)
    WITH 1 COLUMN SIDE-LABELS.
END.

OUTPUT CLOSE.

DISPLAY "Finished".
```

Notes

- The default output destination is the destination that was active when the procedure began. The output destination is usually the terminal unless the current procedure was called by another procedure while a different destination was active.

- A form feed (new page) is automatically output when a PAGED output stream is closed.

- If the output destination is the Windows clipboard, this statement writes all buffered output data to the clipboard in CF-TEXT format and clears the buffer.

- For more information on directing output, see *OpenEdge Development: Programming Interfaces*.

See also

DEFINE STREAM statement, OUTPUT TO statement, Stream object handle

OUTPUT THROUGH statement

Identifies a new output destination as the input to a process that the AVM starts.
OUTPUT THROUGH statement

Syntax

```
OUTPUT [ STREAM stream | STREAM-HANDLE handle ] THROUGH
{ program-name | VALUE ( expression ) }
[ argument | VALUE ( expression ) ] ...
[ ECHO | NO-ECHO ]
[ MAP protermcap-entry | NO-MAP ]
[ PAGED ]
[ PAGE-SIZE { constant | VALUE ( expression ) } ]
[ UNBUFFERED ]
[ NO-CONVERT
  | { CONVERT
    [ TARGET target-codepage ]
    [ SOURCE source-codepage ]
  ]
]
```

STREAM stream

The name of a stream. If you do not name a stream, the AVM uses the unnamed stream. See the DEFINE STREAM statement reference entry and the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams.

STREAM-HANDLE handle

Specifies the handle to a stream. If handle is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams and stream handles.

program-name

The name of the program to which you are supplying data from a procedure. This can be a standard command or your own program.

VALUE ( expression )

An expression whose value is the name of a UNIX program to which you are supplying data from a procedure. An expression is also the argument that you want to pass to the UNIX program. OUTPUT THROUGH passes the value of expression as a character string.

argument

An argument you want to pass to the UNIX program. The OUTPUT THROUGH statement passes this argument as a character string.

If the argument is the literal value paged, page-size, echo, no-echo, or unbuffered, you must enclose it in quotes to prevent the AVM from using that argument as one of the PAGED, PAGE-SIZE, ECHO, NO-ECHO, or UNBUFFERED options for the OUTPUT THROUGH statement.
ECHO

Sends all input data read from a file to the UNIX program. The AVM echoes data by default.

NO-ECHO

Suppresses the echoing of input data to the UNIX program.

MAP protermcap-entry | NO-MAP

The protermcap-entry is an entry from the PROTERMCAP file. Use MAP to send output to a device that requires different character mappings than those in effect for the current output stream. Typically, protermcap-entry is a slash-separated combination of a standard device entry and one or more language-specific add-on entries (MAP laserwriter/french or MAP hp2/spanish/italian, for example). The AVM uses the PROTERMCAP entries to build a translation table for the stream. Use NO-MAP to make the AVM bypass character translation altogether. See OpenEdge Deployment: Managing ABL Applications for more information on PROTERMCAP. See OpenEdge Development: Internationalizing Applications for more information on national language support.

PAGED

Formats the output into pages.

PAGE-SIZE { constant | VALUE ( expression ) }

Specifies the number of lines per page. The expression is a constant, field name, variable name, or expression whose value is an integer. The default number of lines per page is 56. If you use the TERMINAL option to direct output to the terminal, the default number of lines per page is the number of lines of TEXT widgets that fit on the screen. If you specify a non-zero value for PAGE-SIZE, then the PAGED option is assumed. If you specify PAGE-SIZE 0, the output is not paged.

UNBUFFERED

 Writes one character at a time to a normally buffered data source, such as a file. Use the UNBUFFERED option only when you can intermingle your UNIX output (with the ABL UNIX statement) and your ABL output (with the OUTPUT THROUGH statement). That is, the OUTPUT THROUGH statement manages the buffering of output between the ABL procedure the UNIX program that it invokes, but it does not handle the buffering of output to any other programs that the ABL procedure might also invoke.

CONVERT

Allows you to modify the character conversions occurring between the UNIX program and ABL. By default, the OUTPUT TO statement converts characters from the code page specified with the Internal Code Page (-cpinternal) parameter to the code page specified with the Stream Code Page (-cpstream) parameter.

If you specify SOURCE source-codepage alone, the conversion accepts source-codepage as the code page name used in the AVM memory (instead of -cpinternal).

If you specify TARGET target-codepage, the conversion accepts target-codepage as the code page of the UNIX program (instead of -cpstream).
If you specify both SOURCE source-codepage and TARGET target-codepage, it converts characters from the source-codepage to target-codepage (instead of -cpinternal to -cpstream).

**TARGET target-codepage**

Specifies the target code page of the character conversion (replacing -cpstream). The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management).

**SOURCE target-codepage**

Specifies the source code page of the character conversion (replacing -cpinternal). The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management).

**NO-CONVERT**

Specifies that no character conversions occur between the external file and ABL. By default, the OUTPUT THROUGH statement converts characters from the -cpinternal code page to the -cpstream code page.

**Examples**

In this example, the Customer names are displayed. This output is sent as input to the UNIX wc (word count) command. The output of wc is directed to the file wcdata using the standard UNIX redirection symbol (>). Finally, the results are displayed as three integers that represent the number of lines, words, and characters that were in the data sent to wc.

**r-othru.p**

```plaintext
OUTPUT THROUGH wc > wcdata.
/* Word count UNIX utility */
FOR EACH Customer NO-LOCK:
    DISPLAY Customer.Name WITH NO-LABELS NO-BOX.
END.

OUTPUT CLOSE.
PAUSE 1 NO-MESSAGE.
UNIX cat wcdata.
UNIX SILENT rm wcdata.
```

The `r-othru2.p` procedure uses the UNIX crypt program, which accepts lines of data, applies an algorithm based on an encryption key and writes the result to the UNIX standard output stream, that can be directed to a file. The output from the procedure is directed to crypt, which encrypts the customer names based on the password, mypass. The results of the encryption are stored in the ecust file. Then, the AVM decrypts and displays this file.

**r-othru2.p**

```plaintext
OUTPUT THROUGH crypt mypass > ecust.
FOR EACH Customer NO-LOCK WHERE Customer.CustNum < 10:
    DISPLAY Customer.Name WITH NO-LABELS NO-BOX.
END.

OUTPUT CLOSE.
UNIX crypt mypass <ecust.
```
Notes

- When you use the OUTPUT CLOSE statement to close an output destination used by an OUTPUT THROUGH statement, the AVM closes the pipe, waits one second, and then continues.

- For any character conversions to occur, all of the necessary conversion tables must appear in convmap.cp (a binary file that contains all of the tables that ABL uses for character management).

- If you specify a value of “undefined” for either source-codepage or target-codepage, no character conversion is performed.

- For more information on output destinations, see OpenEdge Development: Programming Interfaces.

See also
DEFINE STREAM statement, OUTPUT CLOSE statement, OUTPUT TO statement, Stream object handle

OUTPUT TO statement

Specifies the new output destination for a stream.

Syntax

```plaintext
OUTPUT [ STREAM stream | STREAM-HANDLE handle ] TO
{ PRINTER [ printer-name ]
  | oopsys-file
  | oopsys-device
  | TERMINAL
  | VALUE ( expression )
  | "CLIPBOARD"
}
[ LOB-DIR { constant | VALUE ( expression ) } ]
[ NUM-COPIES { constant | VALUE ( expression ) } ]
[ COLLATE ]
[ LANDSCAPE | PORTRAIT ]
[ APPEND ]
[ BINARY ]
[ ECHO | NO-ECHO ]
[ KEEP-MESSAGES ]
[ NO-MAP | MAP protermcap-entry ]
[ PAGED ]
[ PAGE-SIZE { constant | VALUE ( expression ) } ]
[ UNBUFFERED ]
[ NO-CONVERT
  | { CONVERT
      [ TARGET target-codepage ]
      [ SOURCE source-codepage ]
   }
]
```
OUTPUT TO statement

STREAM stream

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream. See the DEFINE STREAM statement reference entry and the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams.

STREAM-HANDLE handle

Specifies the handle to a stream. If handle is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams and stream handles.

PRINTER [ printer-name ]

By default, this option sends output to the printer defined in the default print context. Specify a printer name to send output to a specific printer. Specifying a printer name overrides, but does not change, the printer defined in the default print context.

When you use this option, it implies that the device you are sending output to is paged, unless you also specify PAGE-SIZE 0.

In Windows, you must specify network printers in Universal Naming Convention format. For example:

```
\\fs_dev\hp\has4
```

On UNIX, the printer spooling facilities (lp or lpr) are used automatically.

opsys-file

The absolute or relative pathname of a file to which you want to direct output. If you specify a relative pathname, the AVM locates the pathname relative to the current working directory. The pathname can contain up to 255 characters. If a file with the specified pathname already exists, the AVM overwrites it.

opsys-device

Represents the name of an operating system device.

TERMINAL

Indicates that you want to direct output to the terminal. The terminal is the default output destination.

VALUE ( expression )

Represents an expression whose value is the destination to which you want to send data.

"CLIPBOARD" (graphical interfaces only)

Specifies the system clipboard as the output destination. The quotes are required.
LOB-DIR \{ \text{constant} \mid \text{VALUE (expression)} \}\}

Specifies the directory in which you want the EXPORT statement to write large object data files (such as BLOB and CLOB data files). The constant and expression arguments are character expressions that evaluate to an absolute pathname or a relative pathname (relative to the directory specified in opsys-file).

If the specified character expression evaluates to either the Unknown value (?) or a directory that does not exist, or you do not have permission to write to the specified directory, the AVM raises the ERROR condition.

The LOB-DIR option is valid only when you specify an operating system file as the output destination.

NUM-COPIES \{ \text{constant} \mid \text{VALUE (expression)} \}\}

Specifies the number of copies to print. The constant or expression parameters must evaluate to a positive integer. This option is supported in Windows only, and only with printer drivers that support multi-copy printing. Specifying the number of copies to print overrides, but does not change, the number of copies defined in the default print context.

The following statement prints three copies of each output page on the selected printer:

```
OUTPUT TO PRINTER NUM-COPIES 3.
```

COLLATE

Specifies whether multiple copies of output pages print in collated order. This option is supported in Windows only, and only with printer drivers that support collation.

LANDSCAPE

Specifies a landscape page orientation. This option is supported in Windows only, and only with printer drivers that support landscape page orientation. Specifying a page orientation overrides, but does not change, the page orientation defined in the default print context.

The following statement prints three copies of each output page with a landscape orientation on the selected printer:

```
OUTPUT TO PRINTER LANDSCAPE NUM-COPIES 3.
```

PORTRAIT

Specifies a portrait page orientation. This option is supported in Windows only, and only with printer drivers that support portrait page orientation. Specifying a page orientation overrides, but does not change, the page orientation defined in the default print context.

APPEND

Appends the output to the end of a file.
OUTPUT TO statement

BINARY

Allows output to be written directly without any conversion or interpretation.

ECHO

Sends all input data read from a file to the output destination. Data is echoed by default.

NO-ECHO

Suppresses the echoing of input data to the output destination.

KEEP-MESSAGES

Causes the following messages not to echo to the default window: ABL error and warning messages, and messages from the MESSAGE statement. If you specify KEEP-MESSAGES, these messages are sent only to the output stream you specify.

MESSAGE statements using the VIEW AS ALERT BOX option are an exception. The KEEP-MESSAGES option does not suppress the message box if there is a way available to display it.

MAP protermcap-entry | NO-MAP

The protermcap-entry value is an entry from the PROTERMCAP file. Use MAP to send output to a device that requires different character mappings than those in effect for the current output stream. Typically, protermcap-entry is a slash-separated combination of a standard device entry and one or more language-specific add-on entries (MAP laserwriter/french or MAP hp2/spanish/italian, for example). The AVM uses the PROTERMCAP entries to build a translation table for the stream. Use NO-MAP to make the AVM bypass character translation altogether. See OpenEdge Deployment: Managing ABL Applications for more information on PROTERMCAP. See OpenEdge Development: Internationalizing Applications for more information on national language support.

PAGED

Formats the output into pages. Form feeds are represented by ^L (CTRL+L). When output is PAGED, a page break occurs every 56 lines. PAGED is automatic for output to a printer.

PAGE-SIZE { constant | VALUE ( expression ) }

Specifies the number of lines per page. The expression is a constant, field name, variable name, or expression whose value is an integer. The default number of lines per page is 56. If you are using the TERMINAL option to direct output to the terminal, the default number of lines per page is the number of lines of TEXT widgets that fit in the window. If you specify a non-zero value for n, then the PAGED option is assumed. If you specify PAGE-SIZE 0, the output is not paged in character mode; in a graphical interface, the default page size is used.

UNBUFFERED

Writes one character at a time to a normally buffered data source, such as a file. Use the UNBUFFERED option only when you can intermingle your UNIX output (with the ABL UNIX statement) and your ABL output (with the OUTPUT TO statement). That is, the OUTPUT TO statement manages the buffering of output between the ABL procedure the UNIX program that it invokes, but it does not handle the buffering of output to any other programs that the ABL procedure might also invoke.
CONVERT

Allows you to modify the character conversions occurring between the external file and memory. By default, the OUTPUT TO statement converts characters from the code page specified with the Internal Code Page (-cpinternal) parameter to the code page specified with the Stream Code Page (-cpstream) parameter. If you specify SOURCE source-codepage alone, the conversion accepts source-codepage as the code page name used in memory (instead of -cpinternal). If you specify TARGET target-codepage, the conversion accepts target-codepage as the code page of the external file (instead of -cpstream). If you specify both SOURCE source-codepage and TARGET target-codepage, it converts characters from the source-codepage to target-codepage (instead of -cpinternal to -cpstream).

TARGET target-codepage

Specifies the target code page of the character conversion (replacing -cpstream). The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management).

SOURCE target-codepage

Specifies the source code page of the character conversion (replacing -cpinternal). The name that you specify must be a valid code page name available in the DLC/convmap.cp file (a binary file that contains all of the tables that ABL uses for character management).

NO-CONVERT

Specifies that no character conversions occur between the external file and memory. By default, the OUTPUT statement converts characters from the -cpinternal code page to the -cpstream code page.

Examples

The r-out.p procedure sends Customer data to a file. The OUTPUT TO statement directs subsequent output to a file, so all statements that normally send output to the terminal send output to that file. After all the Customer data has been displayed to the file, the OUTPUT CLOSE statement resets the output destination to its previous state, usually the terminal. The final DISPLAY statement displays Finished on the terminal because that is the new output destination.

r-out.p

```
OUTPUT TO cust.dat.

FOR EACH Customer NO-LOCK:
        Customer.City Customer.State Customer.Country SKIP(2)
    WITH 1 COLUMN SIDE-LABELS.
END.

OUTPUT CLOSE.
DISPLAY "Finished".
```

The r-termpg.p procedure sends Customer data to the terminal. The OUTPUT TO TERMINAL PAGED statement directs output to the terminal in a paged format; all statements send output to the terminal one page at a time.
**r-term.p**

```abl
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
OUTPUT TO TERMINAL PAGED.
FOR EACH Customer NO-LOCK BREAK BY Customer.SalesRep:
  FIND SalesRep OF Customer NO-LOCK.
  FORM HEADER TODAY
    "Customer Listing For " TO 43
    "Page " TO 55 PAGE-NUMBER - ix TO 58 FORMAT "99"
    (SalesRep.RepName) FORMAT "x(30)" AT 25
    WITH FRAME hdr PAGE-TOP CENTERED.
  VIEW FRAME hdr.
  DISPLAY Customer.CustNum COLUMN-LABEL "Customer!Number"
        Customer.Name LABEL "Name"
        Customer.Phone COLUMN-LABEL "Phone!Number" WITH CENTERED.
  IF LAST-OF(Customer.SalesRep) THEN DO:
    ix = PAGE-NUMBER.
    PAGE.
  END.
END. /* FOR EACH Customer */
OUTPUT CLOSE.
```

**Notes**

- Any ABL statement or construct with the option to output data to a stream can write to the stream specified by this statement.

- The OUTPUT TO TERMINAL statement is the default unless the procedure was called by another procedure while a different output destination was active. The output destination at the beginning of the procedure is the current output destination of the calling procedure.

- The OUTPUT TO TERMINAL PAGED statement clears the screen and displays output on scrolling pages the length of the screen. The AVM pauses before each page header. You can alter the pause using the PAUSE statement.

- ABL can display paged output to the terminal for frames that are wider than the width of the screen. The output is wrapped.

- To send output to a file correctly, you must specify the STREAM-IO option of the Frame phrase for any frame you use to write the file.

- If you send data to a file and you plan to use that data file later as input to a procedure, consider using the EXPORT statement. See the INPUT FROM statement reference entry for more information.

- If you send output to a device other than the terminal, ROW options in Frame phrases have no effect. ROW options also have no effect when you send output to a PAGED terminal. If you do not use the NO-BOX option with a Frame phrase, the AVM omits the bottom line of the box, converts the top line to blanks, and ignores the sides of the box.

- All messages, including Compiler error messages and messages produced by the MESSAGE statement, are sent to the current output destination.

- If the field being output is MEMPTR, you must use the BINARY and NO-CONVERT mode of operation to prevent your data from becoming corrupted if it contains binary data.
• With the BINARY and NO-CONVERT options, you will not get a translation of new-lines to the appropriate characters for your operating system and there will be no code page conversion between -cpinternal and -cpstream.

• If the field being output is MEMPTR and your MEMPTR contains ASCII data you may want code page conversion. However, you cannot get conversion by using the CONVERT parameter on the MEMPTR. You can get code page conversion by using the MEMPTR with the GET-STRING and CODEPAGE-CONVERT functions and the PUT-STRING statement.

• On UNIX, if you want to use a print spooler with spooler options, you can use the Printer (-o) startup parameter to specify the options. See OpenEdge Deployment: Startup Command and Parameter Reference for more information on the Printer startup parameter.

• You must use a printer control sequence to change the number of lines per page produced by your printer.

• Unless otherwise specified, the OUTPUT TO PRINTER statement uses the default print context to determine the printer name, number of copies, and page orientation for a print job. If there is no default print context, the AVM uses the printer control settings from the current environment.

• Use the SYSTEM-DIALOG PRINTER-SETUP statement to let users change the default print context through the Windows Print dialog box.

• Use the PRINTER-NAME attribute of the SESSION system handle to set the printer name in the default print context without user intervention.

• In Windows, the OUTPUT TO statement uses the PrinterFont settings in the current environment (either the Registry, or the [Startup] section of the initialization file) to define a font for a print job. The PrintFont settings are similar to the Font settings in the environment and take the following form:

**Syntax**

```
PrinterFont [ n ] = facename
[ , size = screen-point-size ]
```

OUTPUT TO PRINTER uses the PrinterFont setting. OUTPUT TO LPTn uses the corresponding PrinterFontn entry. The **facename** parameter in a PrinterFont setting represents any valid Windows font supported on your system. If you specify a font that your printer does not support, printing might take a long time and yield unexpected results. The **screen-point-size** setting represents the point size, in screen units, for the font. The AVM converts the point size to logical printer units.

• OUTPUT TO PRINTER in Windows performs the following processing:
  – Checks the default print context. If there is no default print context, the AVM checks the Windows printer control settings from the current environment. If no printer controls are set, the AVM displays an error message and terminates the print operation.
OUTPUT TO statement

- Checks the current environment (either the Registry, or the [Startup] section of the initialization file) for a PrinterFont setting. If there is a valid PrinterFont setting, the AVM uses the font specified for the print job. If there is no PrinterFont setting or the setting specifies a non-existent font, the AVM uses the default printer font for the job. If there is no point size specified for the font in the PrinterFont setting, the AVM uses the default size for the printer.

- OUTPUT TO LPT\text{\textit{n}} in Windows performs the following processing:
  - Checks the ports settings in Windows for a definition of the specified LPT port. If there is no definition of the specified port, the AVM displays an error message and terminates the print operation. If multiple definitions exist for a port, the AVM uses the first definition that it finds.
  - Checks the current environment (either the Registry, or the [Startup] section in the initialization file) for a corresponding PrinterFont setting (PrinterFont1 is for LPT1, etc.). If there is a valid corresponding PrinterFont setting, the AVM uses the font specified for the print job. If there is no corresponding PrinterFont setting or the setting specifies a non-existent font, the AVM uses the "courier new" font for the job and calculates the font height to fit 60 lines on a page. If there is no point size specified for the font in the PrinterFont setting, the AVM uses the default size for the printer.
  - Defines a header at the top of each page in the output. The size of the header is based upon the following calculation: \(1.5 \times \text{font\-height}\).

- In Windows only, OUTPUT TO "CLIPBOARD" buffers all output to the specified stream until the next OUTPUT CLOSE for that stream. The OUTPUT CLOSE statement then writes the output to the Windows clipboard in CF-TEXT format. You can buffer only up to 64K of data between any stream-related pair of OUTPUT TO "CLIPBOARD" and OUTPUT CLOSE statements. Any additional buffered data is lost.

For information on providing additional clipboard reading and writing capabilities to your application, see OpenEdge Development: Programming Interfaces and the CLIPBOARD system handle reference entry.

- For any character conversions to occur, all of the necessary conversion tables must appear in convmap.cp (a binary file that contains all of the tables that ABL uses for character management).

- If you specify a value of “undefined” for either source-codepage or target-codepage, no character conversion is performed.

- The OpenEdge ADE toolset provides a portable solution for printing text files. The solution is a procedure called _osprint.p and it is located in the adecmm directory in the OpenEdge product directory (DLC). The _osprint.p procedure sends a specified text file to the default printer as paged output. For more information on the _osprint.p procedure, see OpenEdge Development: Programming Interfaces.

- For more information on changing your output destination, see OpenEdge Development: Programming Interfaces.

**See also** CLIPBOARD system handle, DEFINE STREAM statement, INPUT-OUTPUT CLOSE statement, PAGE-SIZE function, SESSION system handle, Stream object handle, SYSTEM-DIALOG PRINTER-SETUP statement
OVERLAY statement

Inserts content from a specified expression into a field or variable replacing existing characters, bytes, or columns.

Syntax

\[
\text{OVERLAY ( target, position [, length [, type ]] ) = expression}
\]

target

The name of a CHARACTER field or variable, or a LONGCHAR variable, that you want to overlay with the expression.

position

An integer expression that indicates the first position in the target where you want to overlay the expression. The value of the position must be positive. If the position is longer than the target, ABL pads the target with blanks to match the position.

length

An integer expression that indicates the number of positions you want to allocate for the storage of the expression. The expression is truncated or padded with blanks to match length. If you do not use the length argument or specify -1 as the length, OVERLAY uses the entire expression.

type

A character expression that directs ABL to interpret the specified position and length values as character units, bytes, or columns. A double-byte character registers as one character unit. By default, ABL interprets the specified position and length values as character units.

There are three valid types: "CHARACTER," "RAW," and "COLUMN." The expression "CHARACTER" specifies character units. The expression "RAW" specifies bytes. The expression "COLUMN" specifies display or print character-columns. If you specify the type as a constant expression, ABL validates the type specification at compile time. If you specify the type as a non-constant expression, the AVM validates the type specification at run time.

Note: If the target is a LONGCHAR expression, "CHARACTER" is the only valid type.

expression

A CHARACTER or LONGCHAR expression that results in a character string you want to overlay on the target. If you specify the length, the expression is truncated or padded with blanks to match the length.
OVERLAY statement

Example

The r-replc1.p procedure lets you search for, and replace text strings in a paragraph in a window. When you run the procedure, you see the paragraph, which is an array with an extent of five. You also see a prompt. Enter the text string you want the system to search for, and the new text you want in its place. The procedure searches the paragraph, one line at a time, for the text you entered. The procedure uses the OVERLAY statement to replace the string of old text with the string of new text. The procedure also determines the length of the old text and the new text.

r-replc1.p

```
DEFINE VARIABLE chktext AS CHARACTER NO-UNDO.
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE chkndx AS INTEGER NO-UNDO.
DEFINE VARIABLE ndx AS INTEGER NO-UNDO.
DEFINE VARIABLE old-text AS CHARACTER NO-UNDO.
DEFINE VARIABLE new-text AS CHARACTER NO-UNDO.
DEFINE VARIABLE max-len AS INTEGER NO-UNDO.
DEFINE VARIABLE comment AS CHARACTER NO-UNDO FORMAT "x(49)" EXTENT 5
   INITIAL ["You are probably interested in OpenEdge because",
   "you have a lot of information to organize. You",
   "want to get at the information, add to it, and",
   "change it, without a lot of work and aggravation.",
   "You made the right choice with OpenEdge."]

DISPLAY comment WITH CENTERED FRAME comm NO-LABELS
   TITLE "Why You Chose OpenEdge" ROW 4.

REPEAT:
   SET old-text LABEL "Enter text to search for"
   new-text LABEL "Enter text to replace with"
   WITH FRAME replace SIDE-LABELS CENTERED.

   max-len = MAXIMUM(LENGTH(old-text), LENGTH(new-text)).
   DO ix = 1 TO 5:
      ndx = 1.
      DO ndx = 1 TO LENGTH(comment[ix]):
         chktext = SUBSTRING(comment[ix], ndx).
         chkndx = INDEX(chktext, old-text).
         IF chkndx <> 0 THEN DO:
            ndx = ndx + chkndx - 1.
            OVERLAY(comment[ix], ndx, max-len, "CHARACTER") = new-text.
            ndx = max-len.
         END.
      END.
   DISPLAY comment[ix] WITH FRAME comm.
END.
```

Notes

- The SUBSTRING and OVERLAY statements use the `length` option differently. For both, the `length` indicates how much of the `target` to replace. However, SUBSTRING always inserts the full `expression` and never pads the `expression` to match the `length`. By contrast, the `length` in OVERLAY determines how much ABL adds to the `target`, even if ABL must truncate the `expression` or pad it with spaces. See the r-sub-over.p procedure for an illustration the differences between these two statements.

- Do not split double-byte characters. This statement allows you to overlay either the lead or trail-byte of the target string when you specify "RAW" as the `type` parameter.

See also SUBSTRING function, SUBSTRING statement
PAGE statement

Starts a new output page for PAGED output. No action is taken if output is already positioned at the beginning of a page.

Syntax

```
PAGE [ STREAM stream | STREAM-HANDLE handle ]
```

STREAM stream

Specifies the name of a stream where output is paged. If you do not name a stream, the AVM uses the unnamed stream.

STREAM-HANDLE handle

Specifies the handle to a stream where output is paged. If handle it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed stream.

Example

This procedure prints a customer report, categorized by state, and starts a new page for each state:

```
r-page.p

DEFINE VARIABLE laststate AS CHARACTER NO-UNDO.
OUTPUT TO PRINTER.
FOR EACH Customer NO-LOCK BY Customer.State:
    IF Customer.State <> laststate THEN DO:
        IF laststate <> "" THEN PAGE.
        laststate = Customer.State.
    END.
END.
```

Notes

- If the current output destination is not a paged device (you did not use the PAGED option in the OUTPUT TO statement), the PAGE statement has no effect.

- PAGE has no effect if you are already at the top of a new page.

- If any PAGE-TOP or PAGE-BOTTOM frames are active, they are output prior to the next display.

- For more information on streams and stream handles, see the chapter on alternate I/O sources in *OpenEdge Development: Programming Interfaces*.

See also

DEFINE STREAM statement, OUTPUT TO statement, Stream object handle

PAGE-NUMBER function

Returns the page number of the output destination as an INTEGER value. If the output stream is not paged, PAGE-NUMBER returns a value of 0.
PAGE-SIZE function

Syntax

```
PAGE-SIZE [ ( stream | STREAM-HANDLE handle ) ]
```

**stream**

The name of an output stream. If you do not name a stream, PAGE-SIZE returns the page size of the default unnamed output stream.

**STREAM-HANDLE handle**

The handle to an output stream. If handle it is not a valid handle to a stream, the AVM generates a run-time error.

**Example**

This procedure prints a customer report categorized by state. At the end of each state category, it tests to see if there are at least four lines left on the page. The LINE-COUNTER function returns the current line number of output. If that number plus four is greater than the total number of lines on the page (returned by the PAGE-SIZE function), then the procedure skips to a new page. If there are four or more lines left, the procedure skips a line before printing the next customer record.

```
r-pgnbr.p

OUTPUT TO pagenum.txt PAGED.

FOR EACH Customer NO-LOCK:
  FORM HEADER "Customer report" AT 30
  "Page:" AT 60 PAGE-NUMBER FORMAT ">>9" SKIP(1).
END.
```

See also

DEFINE STREAM statement, OUTPUT TO statement, PAGE statement, Stream object handle

PAGE-SIZE function

Returns the page size (lines per page) of an output destination as an INTEGER value. If the output stream is not paged, PAGE-SIZE returns a value of 0.

Syntax

```
PAGE-SIZE [ ( stream | STREAM-HANDLE handle ) ]
```

**stream**

The name of an output stream. If you do not name a stream, PAGE-SIZE returns the page size of the default unnamed output stream.

**STREAM-HANDLE handle**

The handle to an output stream. If handle it is not a valid handle to a stream, the AVM generates a run-time error.

**Example**

This procedure creates a customer report with a page number on each page:

```
r-pgnbr.p

OUTPUT TO pagenum.txt PAGED.

FOR EACH Customer NO-LOCK:
  FORM HEADER "Customer report" AT 30
  "Page:" AT 60 PAGE-NUMBER FORMAT ">>9" SKIP(1).
END.
```
Parameter definition syntax

Defines one or more run-time parameters for a user-defined function, a class method (including a constructor), or a class event defined with an ABL method signature. ABL implements both scalar and array parameters for user-defined functions and methods of a class as NO-UNDO variables.

Syntax

```
( parameter [ , parameter ] ... )
```

Note: To define run-time parameters for an ABL procedure, Windows dynamic link library (DLL) routine, UNIX shared library routine, or ActiveX control event procedure, see the DEFINE PARAMETER statement reference entry.

Use the following syntax to define each parameter, which can be a primitive, array, class, interface, temp-table, ProDataSet, or buffer:

Syntax

```
{ INPUT | OUTPUT | INPUT-OUTPUT }
{ parameter-name AS { primitive-type-name | [ CLASS ] object-type-name }
  [ EXTENT [ constant ] ]
  | TABLE temp-table-name [ APPEND ] [ BIND ] [ BY-VALUE ]
  | TABLE-HANDLE temp-table-handle [ APPEND ] [ BIND ] [ BY-VALUE ]
  | DATASET dataset-name [ APPEND ] [ BIND ] [ BY-VALUE ]
  | DATASET-HANDLE dataset-handle [ APPEND ] [ BIND ] [ BY-VALUE ]
}
```

```
BUFFER buffer-name FOR database-table-name [ PRESELECT ]
```
**Parameter definition syntax**

**INPUT | OUTPUT | INPUT-OUTPUT**

Specifies the parameter mode, which determines the direction that data travels when the parameter is passed at run time. An INPUT parameter travels from the caller (source), which sets its value, to the called function or method (destination or receiver), which can use the value. An OUTPUT parameter travels from the called function or method (source), which sets its value, back to the caller (destination or receiver), which can use the value. An INPUT-OUTPUT parameter travels both ways, first from the caller, which sets its value; then to the called function or method, which can use and reset the value and pass it back to the caller, which can use the returned value.

**parameter-name**

Specifies the name of a primitive, class, interface, or array parameter.

**AS primitive-type-name**

Specifies a built-in primitive type for the parameter you are defining. The built-in data type (primitive-type-name) can be one of the following:

<table>
<thead>
<tr>
<th>Syntax</th>
</tr>
</thead>
<tbody>
<tr>
<td>CHARACTER</td>
</tr>
<tr>
<td>HANDLE</td>
</tr>
<tr>
<td>ROWID</td>
</tr>
</tbody>
</table>

If you are defining a parameter for a user-defined function, a pure ABL class method (without reference to .NET), or a class event defined with an ABL method signature, **AS-data-type** does not specify a valid primitive type name.

If you are defining a parameter for a method that overrides a .NET super class method (abstract or otherwise) or implements a method defined in a .NET interface, **primitive-type-name** must specify the exact .NET data type of the corresponding parameter in the overridden or implemented method. For a .NET mapped data type that is a default match for a given ABL primitive type, you must use the default matching ABL data type, as shown in Table 23. (For example, INTEGER indicates a .NET System.Int32.) For a .NET mapped data type that is not a default match for one of the ABL primitive types, ABL provides a data type keyword (AS-data-type) that you must use to explicitly indicate the required .NET data type, as shown in Table 24. (For example, the AS data type, UNSIGNED-BYTE, indicates a .NET System.Byte.)

**Note:** At run time, a method parameter defined using an **AS-data-type** keyword behaves in ABL like the corresponding ABL primitive type shown in Table 24. (For example, an UNSIGNED-BYTE behaves like an INTEGER.)

Also note that when overriding or implementing a .NET array parameter, you must specify the .NET array object type (for example, "System.Int32[]" or "System.Byte[]"); you **cannot** use an ABL array equivalent (for example, INTEGER EXTENT or UNSIGNED-BYTE EXTENT).
Parameter definition syntax

**AS** [ **CLASS** ] { **object-type-name** }

Specifies the parameter you are defining as an object reference to a class instance. This can have the data type of a class or an interface.

**object-type-name**

Specifies the type name of an ABL or .NET class or interface. Specify an object type name using the syntax described in the Type-name syntax reference entry. With an appropriate USING statement, you can also specify a class or interface name alone, without the qualifying package or namespace.

You cannot directly specify the type name of a .NET mapped object type (such as System.Int32). To define a parameter that matches a .NET mapped type, you must define it as the corresponding ABL primitive type (**primitive-type-name**).

If you are defining a parameter for a method that overrides a .NET super class method (abstract or otherwise) or implements a method defined in a .NET interface, **object-type-name** must specify the exact .NET object type of the corresponding parameter in the overridden or implemented method. However, for .NET inner (nested) type, note the difference in the ABL syntax, which replaces the corresponding period (.) in the .NET object type with a plus (+) (see the Type-name syntax reference entry).

Also note that when overriding or implementing a .NET array parameter, you must specify the .NET array object type (for example, "System.Drawing.Point[]"); you cannot use an ABL array equivalent (such as System.Drawing.Point EXTENT).

**CLASS**

If the specified class or interface type name conflicts with an abbreviation for a built-in primitive type name, such as INT for INTEGER, you must specify the CLASS keyword.

For a class or interface return value, the AVM passes an object reference associated with the class or interface, not a class instance itself. For more information on object references, see the Class-based object reference reference entry.

**EXTENT** [ **constant** ]

Defines the parameter as an array of data elements with a primitive type (specified using the AS **primitive-type-name** option) or an object type (specified using the AS **object-type-name** option). This option can specify an array parameter as either determinate (has a defined number of elements) or indeterminate (has an undefined number of elements). To define a determinate array parameter, specify the EXTENT option with the **constant** argument. This optional argument is an integer value that represents the number of data elements in the array parameter. To define an indeterminate array parameter, specify the EXTENT option without the **constant** argument.

The EXTENT is part of the parameter data type. For more information, see the Type-name syntax reference entry.

An indeterminate array parameter can be in one of two states: fixed or unfixed, meaning it either has a fixed dimension or it does not. An indeterminate array parameter has an
unfixed dimension when first defined. You can fix the dimension of an unfixed indeterminate array parameter by:

- Setting the number of elements in the array parameter using the EXTENT statement
- Defining the indeterminate array parameter so that it becomes the target of a determinate array assignment as a passed argument (on INPUT) or as a value returned from the method or user-defined function (on OUTPUT), fixing the indeterminate array to the dimension of the determinate array assignment

The AVM treats a fixed indeterminate array parameter as a determinate array parameter; that is, its size is fixed. The AVM determines the size of an unfixed indeterminate array parameter at run time.

If you are using the AS option without the EXTENT option, or you specify constant as 0, the parameter is not an array parameter.

TABLE temp-table-name

Specifies a parameter for a static temp-table.

You can pass a temp-table parameter to both local and remote user-defined functions, as well as to methods of a class. The AVM passes the parameter by value, by default. That is, the caller and the called routine each have their own instance of the temp-table. When you invoke the routine, the AVM deep-copies the parameter from one instance to the other. The table that is copied depends on whether the parameter is INPUT, OUTPUT, or INPUT-OUTPUT. When you pass a temp-table as an INPUT parameter, the AVM replaces the receiving instance with the source instance, by default. You can also append the source instance to the end of the receiving instance by specifying the APPEND option. For more information about the APPEND option, see the option description later in this reference entry.

When passing a temp-table parameter, you can override the default deep copy and pass the parameter by reference or by binding (that is, by passing the parameter using either the BY-REFERENCE or BIND option). Passing a temp-table parameter by reference or by binding allows the caller and the called routine to access the same object instance (instead of deep-copying the parameter).

For more information about passing a temp-table parameter by reference or by binding, see the Parameter passing syntax reference entry. For more information about temp-table parameters, see OpenEdge Getting Started: ABL Essentials.

TABLE-HANDLE temp-table-handle

Specifies a temp-table handle parameter.

DATASET dataset-name

Specifies a parameter for a static ProDataSet.

You can pass a ProDataSet parameter to both local and remote user-defined functions, as well as to methods of a class. The AVM passes the parameter by value, by default. That is, the caller and the called routine each have their own instance of the ProDataSet. When you invoke the routine, the AVM deep-copies the parameter from one instance to the other. The table that is copied depends on whether the parameter is INPUT, OUTPUT, or INPUT-OUTPUT. When you pass a ProDataSet as an INPUT parameter, the AVM
Parameter definition syntax

replaces the receiving instance with the source instance, by default. You can also append the source instance to the end of the receiving instance by specifying the APPEND option. For more information about the APPEND option, see the option description later in this reference entry.

When passing a ProDataSet parameter, you can override the default deep copy and pass the parameter by reference or by binding (that is, by passing the parameter using either the BY-REFERENCE or BIND option). Passing a ProDataSet parameter by reference or by binding allows the caller and the called routine to access the same object instance (instead of deep-copying the parameter).

For more information about passing a ProDataSet object parameter by reference or by binding, see the Parameter passing syntax reference entry. For more information about ProDataSet object parameters, see OpenEdge Development: ProDataSets.

DATASET-HANDLE dataset-handle

Specifies a ProDataSet handle parameter.

APPEND

Specifies whether or not to append the data from a source instance to the receiving instance of a passed temp-table or ProDataSet parameter. To append INPUT parameter data, specify the APPEND option for the parameter in the method or user-defined function definition. To append OUTPUT parameter data, specify the APPEND option for the parameter in the method or function call.

BIND

Indicates that a TABLE, TABLE-HANDLE, DATASET, or DATASET-HANDLE parameter binds a reference-only object in one routine to an object instance defined and instantiated in another local routine.

When you define a reference-only object in the calling routine, and you want to bind that object definition to an object instance in the called routine, define the parameter by specifying the BIND option in an INPUT or INPUT-OUTPUT parameter definition. When you define a reference-only object in the called routine, and you want to bind that object definition to an object instance in the calling routine, define the parameter by specifying the BIND option in an OUTPUT parameter definition. In either case, the reference-only object definition remains bound to the object instance until the routine containing the reference-only object definition is deleted or terminates.

Caution: Do not delete the object or routine to which a reference-only object is bound, or you might be left with references to an object that no longer exists.

You can bind multiple reference-only object definitions to the same object instance. You can also bind a single reference-only object definition to the same object instance multiple times without generating an error. However, you cannot bind a single reference-only object definition to multiple object instances.

When passing one of these parameters to a remote user-defined function, the AVM ignores the BIND option and deep-copies the parameter based on the specified parameter mode.

For more information about passing these parameters by binding, see the Parameter passing syntax reference entry.
BY-VALUE

Specified for an INPUT, OUTPUT, or INPUT-OUTPUT TABLE, TABLE-HANDLE, DATASET, or DATASET-HANDLE parameter in a called routine, this option forces the parameter to be passed to the local routine by value, which overrides any BY-REFERENCE option in the corresponding routine invocation. For more information on BY-REFERENCE, see the Parameter passing syntax reference entry.

BUFFER buffer-name FOR database-table-name [ PRESELECT ]

Defines a buffer parameter, where buffer-name is the name you specify for the buffer and database-table-name is the name of a database table to which the buffer is attached. Note that database-table-name can also specify the name of a temp-table. However, if the temp-table name is identical to a database table name, all ABL references to the database table name must use fully-qualified database-name.database-table-name syntax. A buffer parameter is always INPUT-OUTPUT.

Note: You cannot pass a work table buffer to a buffer parameter.

If you use the PRESELECT option and access the buffer parameter in a DO or REPEAT block, the AVM creates an internal list of the records selected. The PRESELECT option tells the AVM to apply that internal list to the buffer you define.

Note: You cannot invoke a user-defined function remotely if it has one or more buffer parameters. For more information on remote user-defined functions, see OpenEdge Application Server: Developing AppServer Applications.

Notes

• When defining an overloaded method or constructor, the signature must be unique among all overloaded method or constructor definitions, respectively, with the same name. The signature consists of the name of the method or constructor, the number of parameters, and the type and mode of each of its parameters, in order from left to right. The signature of a method does not include the method return type or access mode.

So, overloading allows you to define multiple methods or constructors for a class definition, where all methods or constructors that have the same name all have different signatures. The signature cannot vary only by access mode or return type. If methods within a class definition differ only by their access modes or return types, ABL raises a compilation error.

• For data types that can have an EXTENT for defining arrays, you can define overloaded methods or constructors that are distinguished only by parameters with the same data type, where:

  – One can have the same parameter defined as a primitive (no EXTENT)
  – One can have the same parameter defined with an indeterminate EXTENT
  – Every additional one can have the same parameter defined with a different EXTENT than all the others

• You can have overloaded methods or constructors defined only with TABLE parameters or only with DATASET parameters as long as the corresponding parameter for each
overloaded method or constructor is defined with a different schema from all others defined with the same type.

- TABLE and TABLE-HANDLE parameters count as different data types for overloading, as do DATASET and DATASET-HANDLE parameters. However, because the schema is not known at compile time, you can define only one overloaded method or constructor with a TABLE-HANDLE parameter corresponding to other method or constructor parameters that differ only as TABLE parameters. Similarly, you can define only one overloaded method or constructor with a DATASET-HANDLE parameter corresponding to other overloaded method or constructor parameters that differ only as DATASET parameters.

- At compile time, it might not be possible to identify a unique overloaded method to call that is passed a TABLE-HANDLE or DATASET-HANDLE parameter. Without a schema defined, this parameter type matches any respective TABLE or DATASET parameter, as well as any respective TABLE-HANDLE or DATASET-HANDLE parameter. Where such overloaded alternatives exist, the AVM resolves the correct method to call at run time. For more information, see the Parameter passing syntax reference entry.

- A BUFFER parameter cannot be a REFERENCE-ONLY buffer or a BEFORE-TABLE buffer. Using either of these as a BUFFER type of parameter (as opposed to INPUT or OUTPUT) is a compiler error. Instead of passing the buffer, the buffer's table can be passed by-reference.

See also  CONSTRUCTOR statement, DEFINE EVENT statement, FUNCTION statement, METHOD statement, Parameter passing syntax, SUPER function, Type-name syntax, USING statement

---

**Parameter passing syntax**

Specifies one or more parameters to pass during invocation of an ABL procedure, a user-defined function, a method of a class (ABL or .NET), a class constructor (ABL or .NET), or the built-in Publish( ) event method or PUBLISH statement to publish class or named events, respectively.

**Syntax**

```
( parameter [, parameter ] ... )
```

The parameters specified by `parameter` must match in number and order, according to mode and data type, as required by the given procedure, user-defined function, method, or constructor definition. Use the following syntax to specify each `parameter`:  

---

831
**Parameter passing syntax**

Syntax

```
[ INPUT | OUTPUT | INPUT-OUTPUT ]
{   parm [ AS data-type ]
   |   {   TABLE temp-table-name
       |   TABLE-HANDLE temp-table-handle
       |   DATASET dataset-name
       |   DATASET-HANDLE dataset-handle
   } [ APPEND ] [ BY-VALUE | BY-REFERENCE | BIND ]
}
```

**BUFFER buffer**

```
[ INPUT | OUTPUT | INPUT-OUTPUT ]
```

Specifies the parameter mode. For more information on parameter modes, see the reference entries for the DEFINE PARAMETER statement (for procedures) and the Parameter definition syntax (for user-defined functions, methods, and class events).

Note that for methods and constructors, the parameter mode is optional except for certain overloading conditions. Thus, the default mode depends on the type of invocation, as described in Table 49.

**Table 49: Default parameter passing mode**

<table>
<thead>
<tr>
<th>Invocation type</th>
<th>Default mode</th>
</tr>
</thead>
<tbody>
<tr>
<td>Procedure</td>
<td>INPUT</td>
</tr>
<tr>
<td>User-defined function</td>
<td>Uses the mode defined for the corresponding parameter in the function prototype. For more information on defining prototypes for user-defined functions, see the FUNCTION statement reference entry.</td>
</tr>
</tbody>
</table>
When identifying the parameter mode for a .NET method or constructor, each .NET language uses its own keyword syntax to identify it. Table 50 shows the C# parameter syntax that corresponds to an ABL parameter specified with a given mode. Note that in C#, the default (no keyword) corresponds to the ABL INPUT mode.

### Table 49: Default parameter passing mode

<table>
<thead>
<tr>
<th>Invocation type</th>
<th>Default mode</th>
</tr>
</thead>
<tbody>
<tr>
<td>Method of a class or class constructor</td>
<td>Uses the mode defined for the corresponding parameter in the method or constructor prototype, depending on overloading requirements. For more information on defining prototypes for class-based methods and constructors, see the METHOD statement and CONSTRUCTOR statement reference entries. If the method is overloaded by a given parameter only by mode, you must specify the mode for this parameter in the method call. If you do not do so, ABL raises a compile-time ambiguity error. For example, if a method is overloaded twice by an INTEGER parameter, and the parameter for one method definition has the INPUT mode while the parameter for the other method definition has the OUTPUT mode, you must specify the INPUT keyword if you intend to use the method defined with the INPUT parameter.</td>
</tr>
<tr>
<td>Publish( ) event method</td>
<td>Uses the mode defined for the corresponding parameter in the class event definition. For more information on defining class events, see the DEFINE EVENT statement reference entry.</td>
</tr>
</tbody>
</table>

When identifying the parameter mode for a .NET method or constructor, each .NET language uses its own keyword syntax to identify it. Table 50 shows the C# parameter syntax that corresponds to an ABL parameter specified with a given mode. Note that in C#, the default (no keyword) corresponds to the ABL INPUT mode.

### Table 50: C# syntax matching ABL parameter modes

<table>
<thead>
<tr>
<th>ABL parameter mode</th>
<th>Corresponding C# syntax</th>
</tr>
</thead>
<tbody>
<tr>
<td>INPUT parm</td>
<td>parm</td>
</tr>
<tr>
<td>OUTPUT parm</td>
<td>out parm</td>
</tr>
<tr>
<td>INPUT-OUTPUT parm</td>
<td>ref parm</td>
</tr>
</tbody>
</table>

Also note, as with ABL class-based methods, the default parameter passing modes for calling .NET methods and constructors are based on the parameter passing modes defined for the method or constructor prototypes, depending on overloading. Thus, you must specify the parameter passing mode for each affected parameter if the method is overloaded only by a given parameter’s mode.

**parm**

Specifies the argument passed to the parameter. This can be either an ABL data element or Expression, or a .NET data element, depending on the parameter mode. For an INPUT parameter, parm can be an Expression. For an OUTPUT or INPUT-OUTPUT parameter, parm can be any of the elements defined for the left side of an Assignment (=) statement. For an INPUT-OUTPUT parameter, any property argument must be both writable and readable.
**Note:** Syntactic limitations require that none of the following data items can be an OUTPUT or INPUT-OUTPUT parameter: a writable handle attribute, a writable property (ABL or .NET) on an object reference, or a data member (ABL or .NET) on an object reference. The limitation is that OUTPUT and INPUT-OUTPUT parameters cannot have a colon in their syntax. For example, `OUTPUT myObjectRef:WritableProperty` is invalid syntax.

For procedures, the data type of `parm` must be compatible with the data type defined for the parameter. Procedures allow the matching of a wide variety of different data types between the passed parameter and the parameter definition. When it can, the AVM converts the passed value from the source data type to an appropriate value in the destination data type, depending on the direction (parameter mode) of the passed value. For procedures, the AVM checks data type matching and appropriate overflow conditions at run time.

For user-defined functions, methods of a class, class constructors, and the `Publish( )` event method, the data types of the passed parameter and the parameter definition are validated by the AVM at compile time and must match exactly, unless they have a widening relationship.

The AVM implicitly converts passed parameter values of certain data types from a narrow data type in the source to a widened data type in the destination, depending on the parameter mode. A widened data type is one that can hold all the values of a narrower data type without loss of data. Widening is supported for three related sets of data types, as shown in Table 51, where the arrow (→) indicates the direction that a value can be passed for the parameter.

**Table 51: Data type widening support**

<table>
<thead>
<tr>
<th>Narrower → Wider</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>CHARACTER</td>
<td>–</td>
</tr>
<tr>
<td>INTEGER</td>
<td>INT64</td>
</tr>
<tr>
<td>DATE</td>
<td>DATETIME</td>
</tr>
</tbody>
</table>

Thus, ABL supports the widening of data types in the direction that the parameter is defined, according to its mode:

- **INPUT parameters** — The data type of the passed parameter can be narrower than the defined parameter.
- **OUTPUT parameters** — The data type of the passed parameter can be wider than the defined parameter.
- **INPUT-OUTPUT parameters** — Widening is not supported. Because values are passed in both directions, the data type of the passed parameter must exactly match the data type of the defined parameter.

For .NET method parameters, ABL also supports widening relationships between ABL and some .NET data types. For more information, see the notes of this reference entry.
For a \textit{parm} that involves .NET data types, either as the parameter definition or as the argument, the requirements for parameter passing depend on the parameter and argument data types and the type of routine that defines the parameter. Table 52 shows the possible combinations.

\textbf{Note:} Table 52 refers to .NET value types, .NET mapped data types, .NET arrays of mapped types, boxing, and unboxing. Boxing and unboxing refer to a .NET mechanism for converting between .NET value types and .NET object types. ABL supports a similar mechanism for converting between ABL primitive or array types and a .NET \texttt{System.Object} or compatible array object type. For more information on .NET data types, concepts, and compatibility, see the Data types reference entry.

<td>ABL routine (always)&lt;sup&gt;9&lt;/sup&gt;</td>
<td>On INPUT only, any ABL object and any supported .NET object type except a .NET mapped data type&lt;sup&gt;4&lt;/sup&gt;</td>
</tr>
</tbody>
</table>

1. A .NET mapped data type is any .NET primitive or object type that ABL maps implicitly to an ABL primitive type. For more information, see the Data types reference entry and Table 23.
2. A .NET routine can be a .NET method or constructor.
3. For an ABL or .NET method, the parameter and argument data types must match exactly or map according to the widening rules of the target (on INPUT or OUTPUT) described in this entry. Also note that you cannot pass a System.Object on INPUT to a primitive parameter, because it is a typical narrowing case.
4. You cannot pass parameters where a Progress.Lang.Object is exchanged with a .NET mapped data type, because ABL does not do intermediate boxing or unboxing to a System.Object in order to exchange the value with a Progress.Lang.Object. However, you can pass parameters, exchanging a Progress.Lang.Object with a System.Object (with casting, as appropriate).

5. For an ABL routine, you cannot define parameters (or any data elements) directly as a .NET mapped data type (such as System.Int32). To define parameters that take a .NET mapped type as an argument, you must use the matching ABL primitive type, as shown in Table 23 (such as, INTEGER). However, if an ABL method overrides a .NET method or implements a method of a .NET interface, you must define any .NET parameter that is a .NET mapped type using an ABL keyword (AS data type) that explicitly indicates this .NET type. Also note that this parameter functions at run time as its matching ABL primitive type, not the mapped type as defined by .NET. For more information, see the Parameter definition syntax reference entry.

6. ABL does not automatically box or unbox the value of a .NET System.Object or array object argument passed to a compatible ABL primitive or array parameter of an ABL routine. Also note that you cannot provide a Progress.Lang.Object argument to this parameter on OUTPUT, because an ABL primitive or array, even one with object type elements, is not an object itself and ABL does no boxing to a Progress.Lang.Object.

7. For an INPUT .NET parameter of mapped type elements, because ABL does not have a unique primitive type to match each .NET mapped data type, ABL allows you to box any ABL array whose element type implicitly maps to the elements of the target .NET array, as shown in Table 23. For example, if the parameter is defined as a .NET “System.Int16[]” array object type, you can pass another “System.Int16[]” or an ABL INTEGER array to box, but you cannot pass an ABL INT64 array to box. On INPUT, you also cannot pass an ABL primitive array to a “System.Object[]” parameter, because ABL does not do automatic boxing at the element level of an array object.

8. If the parameter is defined as a .NET value type array (such as, “System.Drawing.Size[]”), the argument must be an identical .NET or ABL array type (such as “System.Drawing.Size[]” or System.Drawing.Size EXTENT). Also, while an INPUT System.Array parameter can take any appropriate .NET or ABL array argument, an INPUT ”System.Object[]” parameter cannot take any ABL array (for .NET methods) or .NET array argument whose element type is an ABL primitive or .NET value type.

9. An ABL routine can be an ABL method, constructor, procedure, or user-defined function.

10. This includes any ABL method that overrides a .NET method or implements a method of a .NET interface.

11. ABL does not automatically box or unbox a compatible ABL primitive or array data type passed to a corresponding .NET System.Object or array object parameter of an ABL routine. On INPUT, you can pass an ABL BOX function call taking a compatible ABL primitive or array type as input. On OUTPUT, you can provide a System.Object or compatible .NET array object argument and then convert it to an ABL primitive or array type by assigning or using the UNBOX function.

12. For a .NET method with an ABL primitive type argument: on INPUT, the AVM boxes the argument value into the default matching .NET object type. With a compatible ABL array argument: on INPUT, the AVM boxes the argument as the corresponding .NET array type.

**AS data-type**

Indicates an explicit mapping between an argument with an ABL primitive type and the parameter of a .NET method or constructor. Assuming that the .NET data type defined for the parameter is compatible with the data type of the ABL argument, data-type represents an ABL keyword (AS data type) that indicates an alternative .NET data type mapping to identify with the .NET parameter. This option is necessary in the following cases:

- When the .NET method or constructor is overloaded by multiple implicit .NET data type mappings for the passed ABL primitive type and the method you want is not identified by the default match for the passed ABL data type. Thus, by explicitly specifying an AS data type, you can disambiguate the implicit .NET overloads for the method or constructor.

**Note:** You can specify a passed parameter AS data type for a .NET method that is not overloaded. However, you have no need to do so unless the method is overloaded by a given parameter.

- The parameter is defined as a System.Object, and you want the .NET value of the passed ABL primitive type to be stored as a .NET mapped data type that is not the default match. For example, you might want the System.Object parameter to store an ABL INTEGER value as a System.Int16 instead of as a System.Int32 (the default match).
For the a list of available keywords that you can specify for *data-type*, as well as the default matches for ABL primitive types with multiple .NET data type mappings, see Table 24 in the Data types reference entry.

**Note:** The AS data types in Table 24 represent some different data types than you can specify using the AS option to pass a COM method parameter. For more information on passing COM method parameters, see the “Syntax for accessing COM object properties and methods” section on page 1278.

---

**TABLE** temp-table-name

Specifies the name of a static temp-table.

This parameter type can match at compile time with any TABLE parameter with the same schema, or any TABLE-HANDLE parameter. If the matching type is TABLE-HANDLE, a run-time check occurs if the TABLE-HANDLE is not the Unknown value (?) in order to ensure that the run-time schemas match. A parameter of a user-defined function or method of a class is verified at compile time, while a parameter of a procedure is verified at run time.

**TABLE-HANDLE** temp-table-handle

Specifies a handle to a temp-table. Use a temp-table handle as a parameter for a dynamic temp-table. The full schema definition behind the handle and the contents of the temp-table are passed unless the temp-table SCHEMA-MARSHAL attribute is set to minimize or prevent schema marshalling.

This parameter type can match at compile time with any TABLE or TABLE-HANDLE parameter. If the matching type is TABLE-HANDLE, a run-time check occurs if the TABLE-HANDLE is not the Unknown value (?) in order to ensure that the run-time schemas match. A parameter of a user-defined function or method of a class is verified at compile time, while a parameter of a procedure is verified at run time.

**DATASET** dataset-name

Specifies the name of a static ProDataSet.

This parameter type can match at compile time with any DATASET parameter with the same schema, or any DATASET-HANDLE parameter. If the matching type is DATASET-HANDLE, a run-time check occurs if the DATASET-HANDLE is not the Unknown value (?) in order to ensure that the run-time schemas match. A parameter of a user-defined function or method of a class is verified at compile time, while a parameter of a procedure is verified at run time.

**DATASET-HANDLE** dataset-handle

Specifies a handle to a ProDataSet. Use a ProDataSet object handle as a parameter for a dynamic ProDataSet. The full schema definition behind the handle and the contents of the ProDataSet object are passed unless the SCHEMA-MARSHAL attribute for one or more of its temp-tables are set to minimize or prevent schema marshalling.

This parameter type can match at compile time with any DATASET or DATASET-HANDLE parameter. If the matching type is DATASET-HANDLE, a run-time check occurs if the DATASET-HANDLE is not the Unknown value (?) in order to ensure that the run-time schemas match. A parameter of a user-defined function or
method of a class is verified at compile time, while a parameter of a procedure is verified at run time.

**BUFFER buffer**

Specifies the name of a buffer.

**APPEND**

Specifies whether or not to append the source temp-table data to the destination temp-table data. To append OUTPUT parameter data, specify the APPEND option for the parameter in the routine call. To append INPUT parameter data, specify the APPEND option for the parameter in the routine definition.

**BY-VALUE | BY-REFERENCE | BIND**

Specifies whether to pass a TABLE, TABLE-HANDLE, DATASET, or DATASET-HANDLE parameter by value, by reference, or by binding. The default is BY-VALUE.

You can pass TABLE, TABLE-HANDLE, DATASET, and DATASET-HANDLE parameters to both local and remote procedures. These parameter types are normally passed by value, by default. That is, the calling routine and the called routine each have their own instance of the object, and the parameter is deep-copied from the calling routine’s instance to the called routine’s instance.

When passing one of these parameters to a local routine, you can override the default in the calling routine by specifying the BY-REFERENCE or BIND option.

Passing one of these parameters to a local routine using the BY-REFERENCE option allows the calling routine and the called routine to access the same object instance. That is, both routines access the calling routine’s instance and ignore the called routine’s instance. Since the called routine’s object instance is ignored, you should define the static object as reference-only by specifying the REFERENCE-ONLY option in the DEFINE statement for the object.

Passing one of these parameters to a local routine using the BIND option allows the calling routine and the called routine to access the same object instance. You can do this by:

- Binding a reference-only static object defined in one routine to an object instance defined in another routine
- Binding an unknown TABLE-HANDLE or DATASET-HANDLE parameter defined in one routine to an object instance defined in another routine

In the static case, you must define a reference-only object in either the calling routine or the called routine by specifying the REFERENCE-ONLY option in the DEFINE statement for the object. You must also define the parameter by specifying the BIND option in the parameter definition.

When you define a reference-only object in the calling routine and pass it to the called routine using the BIND option, the AVM binds the definition of the object in the calling routine to the object instance in the called routine. When you define a reference-only object in the called routine and receive the object from the calling routine, the AVM binds the definition of the object in the called routine to the object instance in the calling routine.
In either case, the reference-only object definition remains bound to the object instance until the routine containing the reference-only object definition is deleted or terminates.

**Caution:** Do not delete the object or routine to which a reference-only object is bound, or you might be left with references to an object that no longer exists.

You can bind multiple reference-only object definitions to the same object instance. You can also bind a single reference-only object definition to the same object instance multiple times without generating an error. However, you cannot bind a single reference-only object definition to multiple object instances.

When passing one of these parameters to a remote procedure, the AVM ignores the BY-REFERENCE and BIND options and deep-copies the parameter based on the specified parameter mode.

**Examples**

The following two code fragments show how the AS data type works when calling an overloaded .NET method, in this case the `System.Math:Max( )` method. This static .NET method compares two values of the same data type and returns the largest of the two. The first fragment compiles and runs. It compares the value 50, passed as a `System.Byte` (specified by the AS data type, UNSIGNED-BYTE), with the maximum value of a `System.Byte`, returned by the `System.Byte:MaxValue` data member. The result returned by the `Max( )` method is 255, the maximum `System.Byte` value:

```
DEFINE VARIABLE iVal1 AS INTEGER NO-UNDO INITIAL 50.
DEFINE VARIABLE iVal2 AS INTEGER NO-UNDO.
DEFINE VARIABLE iReturn AS INTEGER NO-UNDO.

iVal2 = System.Byte:MaxValue.
iReturn = System.Math:Max( INPUT iVal1 AS UNSIGNED-BYTE,
                         INPUT iVal2 AS UNSIGNED-BYTE )..
```

The second fragment compiles, but returns a run-time error. Again, it passes the same two values to the `System.Math:Max( )` method, but this time passes them as a `System.SByte` (specified by the AS data type, BYTE). A signed byte parameter cannot hold positive values as large as an unsigned byte. So, passing the maximum value of a `System.Byte` (unsigned byte) as a `System.SByte` (signed byte) causes the `Max( )` method to raise a run-time overflow error:

```
DEFINE VARIABLE iVal1 AS INTEGER NO-UNDO INITIAL 50.
DEFINE VARIABLE iVal2 AS INTEGER NO-UNDO.
DEFINE VARIABLE iReturn AS INTEGER NO-UNDO.

iVal2 = System.Byte:MaxValue.
iReturn = System.Math:Max( INPUT iVal1 AS BYTE,
                         INPUT iVal2 AS BYTE ). /* Run-time error */
```

The following code fragment shows an example of ABL data type widening when passing parameters to a .NET method. This example shows INPUT widening, in this case, passing different ABL data types (INTEGER and INT64) that are acceptable as arguments to a `System.Double` input parameter:

```
DEFINE VARIABLE iVal1 AS INTEGER NO-UNDO INITIAL 50.
DEFINE VARIABLE iVal2 AS INTEGER NO-UNDO.
DEFINE VARIABLE iReturn AS INTEGER NO-UNDO.

iVal2 = System.Byte:MaxValue.
iReturn = System.Math:Max( INPUT iVal1 AS UNSIGNED-BYTE,
                         INPUT iVal2 AS UNSIGNED-BYTE ).
```
Parameter passing syntax

For more information on data type widening, see the Notes section later in this reference entry.

**Notes**

- The requirements for calling and passing parameters to built-in handle methods and COM object methods have unique features not shared in calls to procedures, user-defined functions, and methods of a class or class constructors. For information on calling and passing parameters to built-in handle methods and COM object methods, see the information on calling these types of methods in the “Handle Attributes and Methods Reference” section on page 1271.

- You do not invoke a class constructor directly. To invoke a constructor, you pass constructor parameters in statements that participate in instantiating the class, such as the NEW function (classes), SUPER statement, or THIS-OBJECT statement. The constructor that is invoked matches the particular signature of the parameters that you pass.

- When you call the Publish() event method to publish a class event, or when you execute the PUBLISH statement to publish a named event, any parameters are passed to every event handler that is subscribed to the event. However, any parameter values returned from the Publish() method or PUBLISH statement reflect the settings of the last event handler to execute. Therefore, when you publish a class or named event, the value returned for an OUTPUT or INPUT-OUTPUT parameter, or for a member of any object (class or handle-based) referenced in an INPUT parameter, depends on the execution order of the event handlers subscribed to the event, which is not guaranteed. In addition, for INPUT-OUTPUT parameters or for members of objects referenced by INPUT parameters, the values returned from each event handler are used as input to the next event handler that executes.

**Caution:** Because the execution order of multiple event handlers subscribed to a single event cannot be guaranteed, if you subscribe more than one event handler to a given class or named event, you cannot be certain which handler will return the values of any parameters that you define for the event.

- You cannot pass a CLOB or BLOB directly as a corresponding LONGCHAR/CHARACTER or MEMPTR parameter. You must first assign the CLOB to a LONGCHAR/CHARACTER or assign the BLOB to a MEMPTR and pass the result. For information on assigning large object data, see the Assignment (=) statement reference entry.

- When you instantiate a class dynamically, using the DYNAMIC-NEW statement, ABL distinguishes overloaded constructors only by the number of parameters.

- When you call overloaded methods or constructors that differ by a parameter that supports widening, ABL looks for an exact data type match at compile time. If an exact match is not found, the compiler will look for the closest widened match.

```
DEFINE VARIABLE i4Val AS INTEGER NO-UNDO.
DEFINE VARIABLE i8Val AS INT64 NO-UNDO.
DEFINE VARIABLE iRoot1 AS DECIMAL NO-UNDO.
DEFINE VARIABLE iRoot2 AS DECIMAL NO-UNDO.

ASSIGN
  i4Val = System.Int32:MaxValue
  i8Val = System.Int64:MaxValue
  iRoot1 = System.Math:Sqrt( INPUT i4Val )
  iRoot2 = System.Math:Sqrt( INPUT i8Val ).
```
When you pass an ABL array parameter, ABL initiates an array assignment that makes a deep copy of the array source to the array target, depending on the parameter mode. For more information on array assignments, see the Assignment (=) statement reference entry.

For INPUT parameters of .NET methods or constructors defined with certain .NET data types, ABL supports widening relationships that allow you to pass ABL arguments with different ABL data types than those supported for implicit mapping to .NET data types (see Table 23 in the Data types reference entry).

Table 53 lists the .NET parameter data types for which ABL supports the widening of ABL data types passed as INPUT arguments. For each .NET parameter data type, the listed ABL implicit mapping data type represents the closest matching ABL data type that you can pass to a .NET input parameter defined with the matching .NET data type. The corresponding listed ABL INPUT widening data types can hold smaller values that might also be acceptable to the .NET input parameter. However, they might also adhere to similar limitations as defined for passing values as the listed ABL implicit mapping data type. (Again, see Table 23 for a more complete description of these limitations.)

Table 53: Data types for .NET INPUT parameter widening

<table>
<thead>
<tr>
<th>.NET parameter object type</th>
<th>C# parameter primitive type</th>
<th>ABL implicit mapping data type</th>
<th>ABL INPUT widening data type</th>
</tr>
</thead>
<tbody>
<tr>
<td>System.DateTime</td>
<td>N/A</td>
<td>DATETIME</td>
<td>DATE</td>
</tr>
<tr>
<td>System.Decimal</td>
<td>decimal</td>
<td>DECIMAL</td>
<td>INTEGER, INT64</td>
</tr>
<tr>
<td>System.UInt32</td>
<td>uint</td>
<td>INT64</td>
<td>INTEGER&lt;sup&gt;1&lt;/sup&gt;</td>
</tr>
<tr>
<td>System.Int64</td>
<td>long</td>
<td>INT64</td>
<td>INTEGER</td>
</tr>
<tr>
<td>System.UInt64</td>
<td>ulong</td>
<td>DECIMAL</td>
<td>INTEGER&lt;sup&gt;1&lt;/sup&gt;, INT64&lt;sup&gt;1&lt;/sup&gt;</td>
</tr>
<tr>
<td>System.Double</td>
<td>double</td>
<td>DECIMAL</td>
<td>INTEGER, INT64</td>
</tr>
<tr>
<td>System.Single</td>
<td>float</td>
<td>DECIMAL</td>
<td>INTEGER&lt;sup&gt;2&lt;/sup&gt;, INT64&lt;sup&gt;2&lt;/sup&gt;</td>
</tr>
</tbody>
</table>

1. If you pass a negative ABL data type to an unsigned data type, the ABL virtual machine (AVM) raises a run-time error.
2. You can lose precision if you pass an ABL INTEGER or INT64 to a System.Single parameter.

For OUTPUT parameters of .NET methods or constructors defined with certain .NET data types, ABL supports widening relationships that allow you to pass ABL arguments with different data types than those supported for implicit mapping to .NET data types (see Table 23 in the Data types reference entry).

Table 54 lists the .NET parameter data types for which ABL supports the widening of ABL data types passed as OUTPUT arguments. For each .NET parameter data type, the listed ABL implicit mapping data type represents the closest matching ABL data type that can hold a .NET value passed to the OUTPUT parameter defined with the matching .NET data type. The corresponding listed ABL OUTPUT widening data types might hold even larger values than the listed ABL implicit mapping data type. However, they might also adhere to similar limitations as defined for the listed ABL implicit mapping data type (Again, see Table 23 for a more complete description of these limitations.)
Table 54: Data types for .NET OUTPUT parameter widening

<table>
<thead>
<tr>
<th>.NET parameter object type</th>
<th>C# parameter primitive type</th>
<th>ABL implicit mapping data type</th>
<th>ABL OUTPUT widening data type</th>
</tr>
</thead>
<tbody>
<tr>
<td>System.Byte</td>
<td>byte</td>
<td>INTEGER</td>
<td>INT64, DECIMAL</td>
</tr>
<tr>

<td>INTEGER</td>
<td>INT64, DECIMAL</td>
</tr>
<tr>
<td>System.Char</td>
<td>char</td>
<td>CHARACTER</td>
<td>LONGCHAR</td>
</tr>
<tr>
<td>System.DateTime</td>
<td>N/A</td>
<td>DATETIME</td>
<td>DATETIME-TZ</td>
</tr>
<tr>
<td>System.Int16</td>
<td>short</td>
<td>INTEGER</td>
<td>INT64, DECIMAL</td>
</tr>
<tr>
<td>System.UInt16</td>
<td>ushort</td>
<td>INTEGER</td>
<td>INT64, DECIMAL</td>
</tr>
<tr>
<td>System.Int32</td>
<td>int</td>
<td>INTEGER</td>
<td>INT64, DECIMAL</td>
</tr>
<tr>
<td>System.UInt32</td>
<td>uint</td>
<td>INT64</td>
<td>DECIMAL</td>
</tr>
<tr>
<td>System.Int64</td>
<td>long</td>
<td>INT64</td>
<td>DECIMAL</td>
</tr>
</tbody>
</table>

- If you are passing an ABL object reference to an OUTPUT or INPUT-OUTPUT parameter defined as an unmapped .NET type, ABL treats any type returned by .NET as a class.

- If you assign a .NET value type object returned as an OUTPUT parameter from a .NET method to an ABL object reference variable, the returned object referenced in ABL is a separate copy from the original value type instance maintained by .NET. However within the ABL session, the object reference to the ABL copy, when passed as a parameter, is passed by reference like any object reference to an ABL class instance.

- ABL allows you to pass ABL arrays (defined with EXTENT) and .NET array objects to each other. Passing an array parameter of any type constitutes an array assignment whose direction moves from the source to the target array according to the parameter mode. How this array assignment works for ABL and .NET array parameters depends upon the types of the source and target arrays. For more information, see the Data types reference entry.

- For temp-table parameters or temp-tables passed as part of a ProDataSet parameter, the AVM does not check for matching temp-table field data types if the SCHEMA-MARSHAL attribute for the temp-table is set to "NONE".

- A BUFFER parameter cannot be a REFERENCE-ONLY buffer or a BEFORE-TABLE buffer. The use of them as a BUFFER type of parameter (as opposed to INPUT or OUTPUT) is a compiler error. Instead of passing the buffer, the buffer's table can be passed by-reference.

- You cannot pass a BUFFER or object reference parameter to a remote procedure. Otherwise, the AVM raises a run-time error.

- You cannot pass DATASET or DATASET-HANDLE parameters to an asynchronous remote procedure.

- If you call a remote procedure asynchronously and pass a parameter as OUTPUT TABLE-HANDLE temp-table-handle APPEND, the event procedure must specify a
corresponding DEFINE INPUT PARAMETER TABLE-HANDLE FOR temp-table-handle APPEND statement, and temp-table-handle must be global to both the calling procedure and the event procedure.

- If you pass a TABLE-HANDLE parameter to a method of a class or a class constructor, where the method or constructor is overloaded with corresponding TABLE-HANDLE and TABLE parameter definitions, the AVM executes the method or constructor that best matches the TABLE-HANDLE parameter. If the schema of the TABLE-HANDLE parameter matches the schema of the TABLE parameter definition, the AVM executes the method or constructor with the TABLE parameter definition. Otherwise, the AVM executes the method or constructor with the TABLE-HANDLE parameter definition.

If you pass a TABLE parameter to a similarly overloaded method or constructor, the AVM executes the method or constructor with a matching TABLE parameter definition. If the AVM cannot identify a method or constructor with a matching TABLE parameter definition, it executes the method or constructor with the corresponding TABLE-HANDLE parameter definition.

If the AVM cannot locate a method or constructor whose temp-table parameter definitions match the corresponding TABLE-HANDLE or TABLE parameter, the AVM raises a run-time error identifying the ambiguity.

- If you pass a DATASET-HANDLE parameter to a method of a class or a class constructor, where the method or constructor is overloaded with corresponding DATASET-HANDLE and DATASET parameter definitions, the AVM executes the method or constructor that best matches the DATASET-HANDLE parameter. If the schema of the DATASET-HANDLE parameter matches the schema of the DATASET parameter definition, the AVM executes the method or constructor with the DATASET parameter definition. Otherwise, the AVM executes the method or constructor with the DATASET-HANDLE parameter definition.

If you pass a DATASET parameter to a similarly overloaded method or constructor, the AVM executes the method or constructor with a matching DATASET parameter definition. If the AVM cannot identify a method or constructor with a matching DATASET parameter definition, it executes the method or constructor with the corresponding DATASET-HANDLE parameter definition.

If the AVM cannot locate a method or constructor whose ProDataSet parameter definitions match the corresponding DATASET-HANDLE or DATASET parameter, the AVM raises a run-time error identifying the ambiguity.

- If you pass a class instance to overloaded methods or constructors whose corresponding class parameters differ only within the same class hierarchy, ABL looks from the bottom of the class hierarchy, starting with the most derived class, and chooses any method or constructor whose corresponding parameters are defined for the same class as the passed parameter. Otherwise, the AVM chooses any method or constructor whose corresponding parameters are defined for the most derived class in the same class hierarchy, which is also a super class of the passed parameter.

- If you pass a class instance to overloaded methods or constructors whose corresponding class parameters differ by one or more interfaces that the class implements, only a method or constructor whose corresponding class parameter exactly matches the class of the passed parameter is acceptable to the compiler. Otherwise, the AVM generates a
compile-time error for ambiguity, as one implemented interface is no better match than another.

- If you pass the Unknown value (?) to a parameter of an overloaded method or constructor, the AVM only selects the correct method or constructor to execute when passing the Unknown value (?) causes no ambiguity among them. Otherwise, the AVM generates a compile-time error for ambiguity.

- If you pass an ABL expression to an overloaded method or constructor whose data type cannot be known at compile-time (for example, the BUFFER-VALUE attribute), the AVM can only call the correct method or constructor at run time, and only when the overloaded method or constructor differs by more than the parameter with an unknown data type. Otherwise, the AVM raises a run-time error for ambiguity.

- You can avoid compile-time ambiguity errors when passing the Unknown value (?) or an expression of an unknown data type in one of two ways:
  - Convert the Unknown value (?) or expression to a specific data type using the appropriate ABL data type conversion function to pass the value.
  - Assign the Unknown value (?) or expression to a variable of a specific data type to pass the value.

- If you pass a method of a class as a parameter to another method, constructor, procedure, or user-defined function that you invoke, and the method parameter executes the RETURN statement with the ERROR option, the method, constructor, procedure, or user-defined function that you invoke does not run. The AVM then raises ERROR on the invoked method, constructor, or procedure. The AVM does not raise ERROR on an invoked user-defined function.

See also  Assignment (=) statement, Expression, FUNCTION statement, NEW function (classes), Publish( ) event method, PUBLISH statement, RUN statement, RUN SUPER statement, SUPER statement, SUPER system reference, THIS-OBJECT statement

---

**PAUSE statement**

Suspends processing indefinitely, or for a specified number of seconds, or until the user presses any key.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
PAUSE
    [ n ]
    [ BEFORE-HIDE ]
    [ MESSAGE message ] [ NO-MESSAGE ]
    [ IN WINDOW window ]
```
PAUSE statement

\[ n \]

A numeric expression specifying the number of seconds that you want to suspend processing. If you do not use this option, the AVM suspends processing until the user presses any key.

**BEFORE-HIDE**

Specifies the pause action the user must take whenever frames are hidden automatically. If you specify \( n \), \( n \) is the number of seconds the AVM pauses before hiding. If you do not specify \( n \), the pause lasts until the user presses a key.

**MESSAGE message**

Displays the message “Press spacebar to continue” on the status line of the terminal screen when the AVM encounters a PAUSE statement. Use the MESSAGE option to override that default message. A *message* is a constant character string.

**NO-MESSAGE**

Tells the AVM to pause but not to display a message on the status line of the terminal screen.

**IN WINDOW window**

Specifies the window to which the pause action applies. The value *window* must be a handle to a window. If you do not use the IN WINDOW phrase, the PAUSE statement applies to the current window.

**Example**

The FOR EACH block in this procedure reads each of the records from the Customer table and displays information from each record. Because the DISPLAY uses a down frame (multiple records displayed in the frame), the AVM usually fills the window with as many records as possible and then displays the message: “Press spacebar to continue”. The PAUSE 2 BEFORE-HIDE message tells the AVM to pause only two seconds before hiding the frame and displaying additional records.

**r-pause.p**

```plaintext
PAUSE 2 BEFORE-HIDE MESSAGE "Pausing 2 seconds".

FOR EACH Customer NO-LOCK WITH 13 DOWN:
END.
```

**Notes**

- After you use PAUSE, that statement is in effect for all the procedures run in that session unless it is overridden by other PAUSE statements in those procedures, or until you return to the Editor.
- Using the PAUSE \( n \) BEFORE-HIDE statement is a good way to write a demonstration application that runs by itself.
- The AVM automatically pauses before removing a frame and displays the “Press spacebar to continue” message if you have not had a chance to see the data in the frame.
- When a PAUSE occurs, the AVM clears any keystrokes buffered from the keyboard, discarding any type-ahead characters.
PDBNAME function

Returns the physical name of a currently connected database.

Syntax

PDBNAME( integer-expression | logical-name | alias )

integer-expression

If the parameter supplied to PDBNAME is an integer expression, and there are, for example, three currently connected databases, then PDBNAME(1), PDBNAME(2), and PDBNAME(3) return their physical names. Also, continuing the same example of three connected databases, PDBNAME(4), PDBNAME(5), etc., return the Unknown value (?).

logical-name | alias

This form of the PDBNAME function requires a quoted character string or a character expression as a parameter. If the parameter is the logical name of a connected database or an alias of a connected database, then the physical name is returned. Otherwise, it returns the Unknown value (?).

Example

This procedure finds the physical name of the database that currently has the DICTDB alias:

```r-pdbnam.p
MESSAGE "The current DICTDB is" PDBNAME("DICTDB") + ".db".
```

Note

The old DBNAME function has been retained for compatibility and is equivalent to PDBNAME(1).

See also

ALIAS function, CONNECT statement, CONNECTED function, CREATE ALIAS statement, CREATE CALL statement, DATASERVERS function, DBCODEPAGE function, DBCOLLATION function, DBRESTRICTIONS function, DBTYPE function, DBCVERSION function, DELETE ALIAS statement, DISCONNECT statement, FRAME-DB function, LDBNAME function, NUM-DBS function, SDBNAME function

PRESELECT phrase

Specifies a set of records to preselect for a DO or REPEAT block.
Syntax

PRESELECT

\[
\begin{align*}
\text{PRESELECT} & \quad \text{record-phrase} \\
 & \quad \text{record-phrase} \quad \ldots \\
 & \quad \text{BREAK} \\
 & \quad \{ \quad \text{BY expression DESCENDING} \\
 & \quad \quad \mid \text{COLLATE (string, strength DESCENDING)} \\
 & \quad \quad \ldots \\
 & \quad \}\ldots \\
\end{align*}
\]

\[
\begin{align*}
\text{record-phrase} & \\
\end{align*}
\]

Goes through a table, selecting records that meet the criteria you specify in \textit{record-phrase}. PRESELECT creates a temporary index that contains pointers to each of the preselected records in the database table. Then you can use other statements, such as FIND NEXT, within the block to process those records.

The \textit{record-phrase} option identifies the criteria to use when preselecting records. Following is the syntax for the \textit{record-phrase}:

Syntax

\[
\begin{align*}
\{ & \quad \text{record} \quad \text{field-list} \} \\
 & \quad \text{constant} \\
 & \quad \left[ \quad \text{LEFT} \quad \text{OUTER-JOIN} \right] \\
 & \quad \text{OF table} \\
 & \quad \text{WHERE expression} \\
 & \quad \text{USE-INDEX index} \\
 & \quad \text{USING \text{FRAME frame field} \ldots} \\
 & \quad \left[ \quad \text{SHARE-LOCK} \mid \text{EXCLUSIVE-LOCK} \mid \text{NO-LOCK} \right] \\
 & \quad \text{NO-PREFETCH} \\
\end{align*}
\]

Specifying multiple occurrences of \textit{record-phrase} preselects the tables using an inner join. Also, any sorting you specify applies to all the tables. If you then do a FIND on the last table in the PRESELECT list, the AVM reads records into the buffers for all of the tables in the list.

For more information on \textit{record-phrase} and inner joins, see the Record phrase reference entry.

BREAK

When used in combination with the FIRST function, LAST function, FIRST-OF function, and LAST-OF function, BREAK indicates that subgroups are used for aggregation. If you use BREAK, you must also use BY.
**PRESELECT phrase**

**BY expression [ DESCENDING ]**

Sorts the preselected records by the value of expression. If you do not use the BY option, PRESELECT sorts the records in order by the index used to extract the records. The DESCENDING option sorts the records in descending order (not in the default ascending order).

**COLLATE ( string, strength [ , collation ] ) [ DESCENDING ]**

Generates the collation value of a string after applying a particular strength, and optionally, a particular collation. The DESCENDING option sorts the records in descending order (not in default ascending order).

- **string**
  - A CHARACTER expression that evaluates to the string whose collation value you want to generate.

- **strength**
  - A CHARACTER expression that evaluates to an ABL comparison strength or an International Components for Unicode (ICU) comparison strength.

The ABL comparison strengths include:

- **RAW** — Generates a collation value for the string based on its binary value.
- **CASE-SENSITIVE** — Generates a case-sensitive collation value for the string based on a particular collation. If you specify this strength with an ICU collation, the AVM applies the ICU TERTIARY strength.
- **CASE-INSENSITIVE** — Generates a case-insensitive collation value for the string based on a particular collation. If you specify this strength with an ICU collation, the AVM applies the ICU SECONDARY strength.
- **CAPS** — Generates a collation value for the string based on its binary value after converting any lowercase letters in the string to uppercase letters, based on the settings of the Internal Code Page (-cpinternal) and Case Table (-cpcase) startup parameters.

The ICU comparison strengths include:

- **PRIMARY** — Generates a collation value for the base characters in the string.
- **SECONDARY** — Generates a collation value for the base characters and any diacritical marks in the string.
- **TERTIARY** — Generates a case-sensitive collation value for the base characters and any diacritical marks in the string.
- **QUATERNARY** — Generates a case-sensitive collation value for the base characters and any diacritical marks in the string, and distinguishes words with and without punctuation. ICU uses this strength to distinguish between Hiragana and Katakana when applied with the ICU-JA (Japanese) collation. Otherwise, it is the same as TERTIARY.
Note: Use ICU comparison strengths only with ICU collations.

collation

A CHARACTER expression that evaluates to the name of an ABL collation table or ICU collation. If collation does not appear, COLLATE uses the collation table of the client.

The AVM reports an error and stops execution if one of the following occurs:

- strength does not evaluate to a valid value.
- collation does not evaluate to a collation table residing in the convmap.cp file.
- collation evaluates to a collation table that is not defined for the code page corresponding to the -cpinternal startup parameter.

Examples
To process a multi-table collection gathered by the PRESELECT option, use the last table named in the collection when you want to read the selected records. The AVM then automatically retrieves records from the other tables.

r-pres11.p

```r-pres11.p
REPEAT PRESELECT EACH Order, Customer OF Order, EACH OrderLine OF Order
   BY Order.OrderDate BY Order.CustNum BY OrderLine.ItemNum:
      FIND NEXT OrderLine.
      DISPLAY Order.OrderDate Order.CustNum Customer.Name OrderLine.ItemNum.
   END.
```

The PRESELECT option in this example selects the logically joined record that consists of Order, OrderLine, and Customer, and makes all of these records available in the REPEAT block. Usually you perform more complex processing within the PRESELECT block.

If, within a PRESELECT block, you find a record using the ROWID of that record, the AVM disregards any other selection criteria you applied to the PRESELECT. For example, suppose the ROWID of Order number 4 is stored in the variable ord-rowid:

```r-pres11.p
DO PRESELECT EACH Order NO-LOCK WHERE Order.OrderNum > 5:
   FIND FIRST Order NO-LOCK WHERE ROWID(Order) = ord-rowid.
   DISPLAY Order.
END.
```

In this example, the AVM finds and displays order number 4 even though the selection criteria specifies that the order number must be greater than 5. The ROWID always overrides other selection criteria. Furthermore, if you use FIND...WHERE ROWID(record) =..., the index cursor is not reset in the preselected list. That is, even if record ROWID(record) is in the preselected list, FIND NEXT does not find the record that follows it in the preselected list.

See also  DEFINE BUFFER statement, DO statement, FIND statement, REPEAT statement
PROC-HANDLE function

Returns a value in the appropriate data type (usually INTEGER) that is a unique identifier for a stored procedure.

Syntax

```
PROC-HANDLE
```

Example

This procedure runs the stored procedure pcust and writes the procedure handle to the variable iHandle. It writes the results of the stored procedure identified by this procedure handle into the ABL-supplied buffer, proc-text-buffer, and displays it.

```
DEFINE VARIABLE iHandle AS INTEGER NO-UNDO.
RUN STORED-PROCEDURE pcust iHandle = PROC-HANDLE (10, OUTPUT 0, OUTPUT 0).
FOR EACH proc-text-buffer WHERE PROC-HANDLE = iHandle:
    DISPLAY proc-text.
END.
CLOSE STORED-PROCEDURE pcust WHERE PROC-HANDLE = iHandle.
```

Notes

- Progress Software Corporation recommends that you specify a procedure handle for each stored procedure that you run.
- You do not have to specify a handle if there is only one active stored procedure and you do not include SQL statements in the ABL application. In the case of ORACLE only, the DataServer passes SQL statements to the ORACLE RDBMS and uses the default system handle in the process.

For more information on using this function, see the OpenEdge DataServer Guides (OpenEdge Data Management: DataServer for Microsoft SQL Server, OpenEdge Data Management: DataServer for ODBC, and OpenEdge Data Management: DataServer for Oracle).

See also

CLOSE STORED-PROCEDURE statement, PROC-STATUS function, RUN STORED-PROCEDURE statement

PROC-STATUS function

Returns the return status from a stored procedure. The return status is an INTEGER value that indicates whether a stored procedure failed and why.

Syntax

```
PROC-STATUS
```

Example

This procedure runs the ORACLE stored procedure pcust and writes the results of the stored procedure into the ABL-supplied buffer, proc-text-buffer. The CLOSE STORED-PROCEDURE statement then retrieves the output parameters. The return status is written to the variable iStat and is displayed. This same code works for accessing a stored procedure from an ODBC-compliant data source:
PROCEDURE statement

Defines an internal procedure as an ABL procedure or declares an internal procedure prototype for an external routine in a Windows dynamic link library (DLL) or UNIX shared library, or for an internal ABL procedure defined in an external procedure that is itself a super procedure of the declaration procedure. The following syntax boxes describe the syntax for each use of the statement, beginning with an internal procedure definition.

Syntax

```abla
PROCEDURE proc-name [ PRIVATE ] :
    [ procedure-body ]
```

This is the syntax to declare an internal procedure prototype for a routine in a Windows DLL or UNIX shared library, or for an internal ABL procedure defined in a super procedure:

Syntax

```abla
PROCEDURE proc-name
    { EXTERNAL "dllname" [ CDECL | PASCAL | STDCALL ]
        [ ORDINAL n ] [ PERSISTENT ]
        | IN SUPER }
    : :
    [ procedure-body ]
```

`proc-name`

The name of the internal procedure.

To define the name of an internal ABL procedure that is an event handler for ActiveX controls (OCX event procedure), you must specify `proc-name` according to the following syntax:

```abla
DEFINE VARIABLE iStat AS INTEGER NO-UNDO.
RUN STORED-PROCEDURE pcust (10, OUTPUT 0, OUTPUT 0).
FOR EACH proc-text-buffer:
END.
CLOSE STORED-PROCEDURE pcust iStat = PROC-STATUS.
DISPLAY iStat.
```
### Syntax

```
{  control-frame-name.control-name.event-name
    |  ANYWHERE.event-name
}
```

For more information on naming event handlers for ActiveX controls using this syntax, see the notes for this reference entry.

**EXTERNAL "dllname"**

Declares the internal procedure as a Windows DLL or UNIX shared library routine. The `dllname` argument, specified as a string literal, is the name of the DLL or library containing the routine.

**CDECL**

Tells ABL to use the C calling convention when accessing the routine.

**PASCAL**

Supported only for backward compatibility. This option is not valid for SpeedScript.

**STDCALL**

Tells ABL to use the standard Windows calling convention when accessing the routine. This is the default.

**ORDINAL n**

Specifies the number of the DLL entry point (the nth routine) to invoke. If you use the ORDINAL option, then `proc-name` can specify any name used in the corresponding RUN statement to reference the routine. If you omit the ORDINAL option, `proc-name` specifies which DLL routine you want to invoke.

For UNIX shared library routines, this option does not apply and is ignored.

**PERSISTENT**

Specifies that the DLL or shared library routine should remain loaded in memory until the AVM exits or the session executes the RELEASE EXTERNAL statement.

**PRIVATE**

Indicates the following about the internal procedure:

- It cannot be invoked from an external procedure—that is, from a procedure file external to the current procedure file.
- The INTERNAL-ENTRIES attribute on the procedure that defines it does not provide its name (unless the procedure that defines it is the current procedure file).
- The GET-SIGNATURE method on the procedure that defines it does not provide its signature (unless the procedure that defines it is the current procedure file).
IN SUPER

Declares that the definition of the internal procedure resides in a super procedure.

procedure-body

The body of an internal procedure definition. Define procedure-body using the following syntax:

**Syntax**

```
procedure-logic
  .
  .
  [ catch-block [ catch-block ... ] ]
  [ finally-block ]
  [ END [ PROCEDURE ] . ]
```

procedure-logic

Zero or more ABL statements, depending on the internal procedure definition or declaration. Each logic statement must end in with a period (.)

If you declare the internal procedure as an ABL procedure, these statements can include executable statements and non-executable statements including definitions of run-time parameters (using the DEFINE PARAMETER statement), local program variables, frames, widgets, and buffers. Any such objects you define within the internal procedure remain in effect only for the life of the internal procedure.

If you are defining the internal procedure for use as an event procedure to handle asynchronous remote requests, you can specify run-time parameters as INPUT only. (Any other type of parameter generates a run-time error.) Each INPUT parameter must correspond in order and data type with an OUTPUT (or INPUT-OUTPUT) parameter as defined in the remote procedure that executes the request. For more information on working with asynchronous remote requests and event procedures, see *OpenEdge Application Server: Developing AppServer Applications*.

If you declare the internal procedure as a DLL or UNIX shared library routine (using the EXTERNAL option), these statements can include only DEFINE PARAMETER statements.

For more information on accessing DLL or UNIX shared library routines from ABL, see the chapter on DLLs in *OpenEdge Development: Programming Interfaces*.

catch-block

Specifies a CATCH statement that defines error handling code for one or more error types. A DO block does not have any default error handling. Therefore, a DO block must have error handling options specified such that it becomes an undoable block. Otherwise, ABL generates a compiler warning. For more information on catch-block, see the CATCH statement reference entry.

finally-block
Specifies a FINALLY statement that defines the processing that must occur after all other processing in the block occurs. For more information on **finally-block**, see the FINALLY statement reference entry.

**END [ PROCEDURE ]**

Specifies the end of the internal procedure body. If *procedure-logic* contains one or more statements, you must end the internal procedure body with the END statement.

**Examples**

The following example declares an ABL internal procedure that computes the factorial of an integer entered as an INPUT parameter. The result is returned as an OUTPUT parameter. Note that the following procedure calls itself recursively to obtain the result:

**r-factrl.p**

```abl
DEFINE VARIABLE FactorialResult AS INTEGER NO-UNDO FORMAT ">>,>>,>>,>>,9".
DEFINE VARIABLE FactorialInput AS INTEGER NO-UNDO.

REPEAT:
  SET FactorialInput VALIDATE(FactorialInput <= 12 AND FactorialInput >= 0, "Value must be between 0 and 12.").
  RUN Factorial (INPUT FactorialInput, OUTPUT FactorialResult).
  DISPLAY FactorialResult.
END.

PROCEDURE Factorial:
  DEFINE INPUT PARAMETER  PTerm AS INTEGER NO-UNDO.
  DEFINE OUTPUT PARAMETER FactorialResult AS INTEGER NO-UNDO.
  DEFINE VARIABLE WorkingResult AS INTEGER NO-UNDO.

  IF PTerm <= 1 THEN DO:
    FactorialResult = 1.
    RETURN.
  END.
  ELSE DO:
    RUN Factorial (INPUT PTerm - 1, OUTPUT WorkingResult).
    FactorialResult = PTerm * WorkingResult.
  END.
END PROCEDURE.
```

The following example declares a DLL routine, `MessageBox()`, which displays a message:

**r-dllex1.p**

```abl
DEFINE VARIABLE iResult AS INTEGER NO-UNDO.
MESSAGE "It's a whole new world!!"
VIEW-AS ALERT-BOX MESSAGE BUTTONS OK TITLE "ABL Message".

RUN MessageBoxA (0, "It's a whole new world, again!!", "ABL DLL Access", 0, OUTPUT iResult).

PROCEDURE MessageBoxA EXTERNAL "user32.dll":
  DEFINE INPUT PARAMETER hwnd AS LONG.
  DEFINE INPUT PARAMETER mbtext AS CHARACTER.
  DEFINE INPUT PARAMETER mbtitle AS CHARACTER.
  DEFINE INPUT PARAMETER style AS LONG.
  DEFINE RETURN PARAMETER result AS LONG.
END.
```
The following code fragment declares a UNIX shared library routine:

```
PROCEDURE atoi EXTERNAL "/usr/lib/libc.so.1":
...
```

**Notes**

- You can terminate a PROCEDURE statement with either a period (.) or a colon (:), but typically use a colon (:) for a procedure definition or prototype that includes `procedure-body` and a period (.) for a procedure definition or prototype that omits any `procedure-body`.

- You can place an internal procedure definition or declaration before, after, or in the middle of your main procedure code. You **cannot** nest an internal procedure within another internal procedure.

- Use the RUN statement to invoke an internal procedure. You can run an internal procedure from within the external procedure that defines it, either from the main-line of the external procedure or from another internal procedure defined in the external procedure. You can also run an internal procedure defined in another external procedure using the IN `proc-handle` option of the RUN statement as long as the external procedure meets one of these conditions:
  - It is active on the procedure call stack
  - It is an instance of a persistent procedure

- You cannot define shared objects, work tables, or temp-tables within an internal procedure.

- An internal procedure can reference any objects defined in the outer procedure block. For example, it can reference variables, buffers (explicit or implicit; shared or unshared), variables, run-time parameters, named frames, or temp-tables. If you define an object with the same name in the internal procedure and the external procedure, a reference within the internal procedure resolves to the local object.

- A buffer explicitly defined in an internal procedure is scoped to the internal procedure. Any other buffers are scoped to the outer procedure block.

- To define the internal procedure as an event handler for ActiveX controls (OCX event procedure), you must specify `proc-name` according to the following syntax:

**Syntax**

```
{
  control-frame-name .control-name .event-name
  | ANYWHERE .event-name
}
```

In `control-frame-name.control-name.event-name`, `control-frame-name` is the name (unquoted) of the control-frame that contains the ActiveX control. This is the name that the AppBuilder typically assigns to the control-frame (NAME widget attribute) when you insert the control into your user interface. The `control-name` is the value (unquoted) that you assign to the control Name property at design time in the AppBuilder Property Window. The `event-name` is the name (unquoted) of the ActiveX control event that you want to trigger execution of this procedure.
In ANYWHERE.event-name, ANYWHERE specifies an event procedure that handles the specified event in any ActiveX control. This event procedure executes only if you have not defined a control-frame-name.control-name.event-name event procedure that exactly matches the control/event combination at run time.

At design time, the AppBuilder lists the available events for a control and automatically creates a template for the OCX event procedure definition from the event that you select. For more information on how to create OCX event procedures in the AppBuilder, see the information on ActiveX controls in *OpenEdge Development: Programming Interfaces*. For more information on how to work with OCX event procedures in an application, see *OpenEdge Development: Programming Interfaces*.

- When you define an OCX event procedure, you can access the component handle (COM-HANDLE value) of the control that generates the event at run time using the COM-SELF system handle. You can also access the handle of the parent control-frame using the SELF system handle.

- The RETURN-VALUE function provides the value returned by the most recently executed RETURN statement of a local or remote procedure.

- You use the call object handle to dynamically invoke a Windows DLL routine or UNIX shared library routine at run time.

See also Call object handle, COM-SELF system handle, DEFINE PARAMETER statement, END statement, RUN statement, TRIGGER PROCEDURE statement

### PROCESS EVENTS statement

Processes all outstanding events without blocking for user input.

### Syntax

```
PROCESS EVENTS
```

### Example

This procedure counts to 1,000 until you choose **STOP**:

```
r-proevs.p
```

```
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE stop-sel AS LOGICAL NO-UNDO.

DEFINE BUTTON stop-it LABEL "STOP".
DISPLAY stop-it.

ON CHOOSE OF stop-it
    stop-sel = TRUE.
END.

ENABLE stop-it.

DO ix = 1 TO 1000:
    DISPLAY ix VIEW-AS TEXT.
    PROCESS EVENTS.
    IF stop-sel THEN LEAVE.
END.
```
On each pass through the loop, the procedure displays the new value of \( i \) and then checks whether any events are waiting to be processed. If no events have occurred, execution continues and the loop iterates. If the STOP button has been chosen, that event is processed changing the value of stop-sel. When execution continues, the program exits the loop.

If the loop does not contain the PROCESS EVENTS statement, the choose event never processes and the loop iterates until \( i \) equals 1,000.

**Notes**
- The WAIT-FOR statement processes all pending events and blocks all other execution until a specified event occurs. The PROCESS EVENTS statement processes all pending events and immediately continues execution with the next statement.
- If there are any asynchronous requests for which PROCEDURE-COMPLETE events have been received but not yet processed, this statement processes these events as described for the WAIT-FOR statement.
- .NET can raise exceptions in the context of an ABL session when this statement executes.

**See also** WAIT-FOR statement (ABL only), WAIT-FOR statement (.NET and ABL)

### PROGRAM-NAME function

Returns the name of the calling program.

**Syntax**

```abl
PROGRAM-NAME(n)
```

\( n \)

The numeric argument. If \( n \) is 1, the name of the current program is returned. If \( n \) is 2, the name of the calling program is returned. If there is no calling program then you have reached the top of the call stack and the AVM returns the Unknown value (?).

**Example**

This procedure returns the names of any procedure(s) that called it, and displays the number of levels that the procedure was nested:

```abl
r-prgnm.p

/* Note this program should be run as a subroutine. */
/* The deeper the nesting, the better the illustration. */

DEFINE VARIABLE level AS INTEGER NO-UNDO INITIAL 1.

REPEAT WHILE PROGRAM-NAME(level) <> ?:
    DISPLAY LEVEL PROGRAM-NAME(level) FORMAT "x(30)".
    level = level + 1.
END.
```

**Notes**
- If you execute a procedure directly from the Procedure Editor or the User Interface Builder, then PROGRAM-NAME(1) returns the name of a temporary file rather than the name of the actual procedure file.
• The PROGRAM-NAME function is useful when developing on-line help. For example, you can use the following code in your help routine to produce a program trace:

```
DEFINE VARIABLE ix AS INTEGER NO-UNDO INITIAL 2.
DEFINE VARIABLE plist AS CHARACTER NO-UNDO FORMAT "x(70)".

FORM plist
  WITH FRAME what-prog OVERLAY ROW 10 CENTERED 5 DOWN NO-LABELS
  TITLE " Program Trace ".
/* ix = 2, so skip the current routine: PROGRAM-NAME(1) */
DO WHILE PROGRAM-NAME(ix) <> ?:
  IF ix = 2 THEN
    plist = "Currently in       : " + PROGRAM-NAME(ix).
  ELSE
    plist = "Which was called by: " + PROGRAM-NAME(ix).
  ix = ix + 1.
  DISPLAY plist WITH FRAME what-prog.
  DOWN WITH FRAME what-prog.
END.
PAUSE.
HIDE FRAME what-prog.
```

• If the procedure you reference is an internal procedure, then PROGRAM-NAME returns a string with the following form:

```
"internal-procedure-name source-file-name"
```

• If the procedure you reference is a user interface trigger associated with a widget, then PROGRAM-NAME returns a string with the following form:

```
"USER-INTERFACE-TRIGGER source-file-name"
```

• If the procedure you reference is a user interface trigger that uses the ANYWHERE keyword, then PROGRAM-NAME returns a string with the following form:

```
"SYSTEM-TRIGGER source-file-name"
```

• If the procedure you reference is a session database trigger, then PROGRAM-NAME returns a string with the following form:

```
"type-TRIGGER source-file-name"
```

Where type is either ASSIGN, CREATE, DELETE, FIND, or WRITE.

• If the call stack contains a method reference, then PROGRAM-NAME returns a string with the following form:
"method-name class-file-name"

Where class-file-name is the name of the class definition (.cls) file in which method-name is implemented.

**PROGRESS function**

Returns one of the following character values which identifies the ABL product that is running: Full, Query or Run-time. Can also return COMPILE if you use the Developer’s Toolkit, or COMPILE-ENCRYPT if you use the run-time Compiler.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
PROGRESS
```

**Examples**

The following procedure uses the PROGRESS phrase function to determine which exit prompt is displayed on a menu:

```
/* Depending on the version of PROGRESS you are running, the main menu reflects available features for end-user */

DEFINE VARIABLE menu AS CHARACTER NO-UNDO EXTENT 3.
DEFINE VARIABLE exit-prompt AS CHARACTER NO-UNDO.

IF PROGRESS EQ "FULL" THEN
exit-prompt = " 3. Return to Full Editor ".
ELSE IF PROGRESS EQ "QUERY" THEN
exit-prompt = " 3. Return to Query Editor ".
ELSE IF PROGRESS EQ "RUN-TIME" THEN
exit-prompt = " 3. Exit Program ".

DO WHILE TRUE:
DISPLAY
"  1. Display Customer Data" @ menu[1] SKIP
"  2. Display Order Data" @ menu[2] SKIP
exit-prompt @ menu[3]
FORMAT "x(26)" SKIP
WITH FRAME choices NO-LABELS.

CHOOSE FIELD menu AUTO-RETURN WITH FRAME choices
TITLE "Demonstration menu" CENTERED ROW 10.
HIDE FRAME choices.

IF FRAME-INDEX EQ 1 THEN MESSAGE
"You picked option 1."
ELSE IF FRAME-INDEX EQ 2 THEN MESSAGE
"You picked option 2."
ELSE IF FRAME-INDEX EQ 3 THEN RETURN.
END.
```

This procedure displays a message that tells you the type of ABL product you are using:
PROMPT-FOR statement

Requests input and places that input in the screen buffer (frame).

The PROMPT-FOR statement is a combination of the following statements:

- **ENABLE** — Enables the specified field-level widgets (in this case fill-in fields) for input
- **WAIT-FOR** — Blocks for input and processes all ABL events until a specific ABL event occurs, in this case the GO universal key function event
- **DISABLE** — Disables the specified field-level widgets (in this case fill-in fields) for input

**Note:** Does not apply to SpeedScript programming.

### Data movement

![Diagram showing data movement between Database, Record buffer, Screen buffer, and User]
PROMPT-FOR statement

Syntax

```
STREAM stream |
STREAM-HANDLE handle |
UNLESS-HIDDEN ]
{ 
  { field
    [ format-phrase ]
    [ WHEN expression ]
  }
  TEXT ( { field
    [ format-phrase ]
    [ WHEN expression ]
  }
  ) ...
}
{ constant
  [ { AT | TO } n ]
  [ VIEW-AS TEXT ]
  [ FGCOLOR expression ]
  [ BGCOLOR expression ]
  [ FONT expression ]
}
{ SPACE [ ( n ) ] | SKIP [ ( n ) ] | ^
} ...
GO-ON ( key-label ... ) ]
IN WINDOW window ]
{ frame-phrase ]
[ editing-phrase ]
```

STREAM stream

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream. See the DEFINE STREAM statement reference entry and the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams.

STREAM-HANDLE handle

Specifies the handle to a stream. If handle it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams and stream handles.
UNLESS-HIDDEN

Restricts PROMPT-FOR to fields whose HIDDEN attribute is FALSE.

field

Specifies the name of the field or variable whose value you want to enter and store in the screen buffer. Remember that the PROMPT-FOR statement only accepts input and stores it in the screen buffer. The underlying record buffer of a field or variable is unaffected.

This field parameter is demonstrated in the following program:

```assembler
DEFINE VARIABLE ix AS INTEGER NO-UNDO INITIAL 3.
PROMPT-FOR ix.
MESSAGE "Record buffer" ix SKIP(0) "Screen buffer" INPUT x.
```

The program does the following:

- Stores the initial value of ix in a record buffer
- Prompts for a new value of ix, and stores the new value in a screen buffer
- Displays the value in the record buffer, retrieves the value in the screen buffer, then displays that

In the case of array fields, array elements with constant subscripts are treated just like any other field. Array fields with no subscripts or in the FORM statement are expanded as though you had typed in the implicit elements. See the DISPLAY statement reference entry for information on how array fields with expressions as subscripts are handled.

format-phrase

Specifies one or more frame attributes for a field, variable, or expression. For more information on format-phrase, see the Format phrase reference entry.

WHEN expression

Prompts for the field only when expression has a value of TRUE. Here, expression is a field name, variable name, or expression that evaluates to a LOGICAL value.

TEXT

Defines a group of character fields or variables (including array elements) to use automatic word-wrap. The TEXT option works only with character fields. When you insert data in the middle of a TEXT field, the AVM wraps data that follows into the next TEXT field, if necessary. If you delete data from the middle of a TEXT field, the AVM wraps data that follows into the empty area.

If you enter more characters than the format for the field allows, the AVM discards the extra characters. The character fields must have formats of the form x(n). A blank in the first column of a line marks the beginning of a paragraph. Lines within a paragraph are treated as a group and will not wrap into other paragraphs.

Table 55 lists the keys you can use within a TEXT field and their actions.
In this procedure, the s-com, or Order Comments field is a TEXT field. Run the following procedure and enter text in the field to see how the TEXT option works:

```
r-text.p
```

```text
DEFINE VARIABLE s-com AS CHARACTER NO-UNDO FORMAT "x(40)" EXTENT 5.

FORM
  "Shipped   :" Order.ShipDate AT 13 SKIP
  "Misc Info :" Order.Instructions AT 13 SKIP(1)
  "Order Comments :" s-com AT 1
  WITH FRAME o-com CENTERED NO-LABELS TITLE "Shipping Information".

FOR EACH Customer NO-LOCK, EACH Order OF Customer:
  DISPLAY Customer.CustNum Customer.Name Order.OrderNum Order.OrderDate
  Order.PromiseDate WITH FRAME order-hdr CENTERED.
  UPDATE Order.ShipDate Order.Instructions TEXT(s-com)
  WITH FRAME o-com.
  s-com = "".
END.
```
PROMPT-FOR statement

constant [ AT n | TO n ] [ VIEW-AS TEXT ] [ FGCOLOR expression ]
[ BGCOLOR expression ] [ FONT expression ]

Specifies a literal value that you want displayed in the frame. If you use the AT option, n is the column in which you want to start the display. If you use the TO option, n is the column in which you want to end the display. You can use the BGCOLOR, FGCOLOR, and FONT options to define the colors and font in which the constant is displayed. If you use the VIEW-AS TEXT option, the constant is displayed as a text widget rather than a fill-in field.

SPACE [ ( n ) ]

Identifies the number (n) of blank spaces to insert after the field is displayed. The n can be 0. If the number of spaces you specify is more than the spaces left on the current line of the frame, a new line is started and any extra spaces are discarded. If you do not use this option or n, one space is inserted between items in the frame.

SKIP [ ( n ) ]

Identifies the number (n) of blank lines to insert after the field is displayed. The n can be 0. If you do not use this option, the AVM does not skip a line between expressions unless the expressions do not fit on one line. If you use the SKIP option, but do not specify n, or if n is 0, the AVM starts a new line unless it is already at the beginning of a new line.

^
Tells the AVM to ignore an input field when input is being read from a file. Also, the following statement will read a line from an input file and ignore that line. This is an efficient way to skip over lines.

GO-ON ( key-label . . . )

The GO-ON option tells the AVM to execute the GO action when the user presses any of the keys listed. The keys you list are used in addition to keys that perform the GO action by default (such as F1 or RETURN on the last field) or because of ON statements.

When you list a key in the GO-ON option, you use the keyboard label of that key. For example, if you want the AVM to take the GO action when the user presses F2, you use the statement GO-ON(F2). If you list more than one key, separate them with spaces, not commas.

IN WINDOW window

Specifies the window in which the prompt occurs. The expression window must resolve to a handle to a window.

frame-phrase

Specifies the overall layout and processing properties of a frame. For more information on frame-phrase, see the Frame phrase reference entry.
**PROMPT-FOR statement**

*editing-phrase*

Supported only for backward compatibility.

Identifies processing to take place as each keystroke is entered. This is the syntax for *editing-phrase*:

**Syntax**

```
[ label : ] EDITING: statement ... END
```

For more information on *editing-phrase*, see the EDITING phrase reference entry.

*record*

The name of a record buffer. All of the fields in the record will be processed exactly as if you prompted for each of them individually.

To use PROMPT-FOR with a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

*EXCEPT field*

Affects all fields except those listed in the EXCEPT phrase.

**Examples**

The *r-prmpt.p* procedure requests a customer number from the user and stores that number in the screen buffer. The FIND statement reads a record from the Customer database table.

*r-prmpt.p*

```
REPEAT:
  PROMPT-FOR Customer.CustNum.
  FIND Customer USING Customer.CustNum NO-ERROR.
  IF NOT AVAILABLE Customer THEN DO:
    MESSAGE "No such customer number.".
    UNDO, RETRY.
  END.
END.
```

The *r-prmpt2.p* procedure requests the initials of a sales representative and stores those initials in the screen buffer. The FIND statement uses the initials stored in the screen buffer to read a record from the SalesRep database table. After finding the record, the procedure displays sales rep information.

*r-prmpt2.p*

```
REPEAT:
  PROMPT-FOR SalesRep.SalesRep LABEL "Sales rep's initials"
    WITH FRAME namefr ROW 2 SIDE-LABELS.
    WITH 1 DOWN NO-HIDE.
END.
```
Notes

- PROMPT-FOR puts user-supplied data into a screen buffer. It does not put any data into a record buffer. Therefore, if you want to use the data in the screen buffer, you must use the INPUT function to refer to the data in the screen buffer or use the ASSIGN statement to move the data from the screen buffer into a record buffer. You can also use the USING option to FIND a record with the screen data index value.

- When ABL compiles a procedure, it designs all the frames used by that procedure. When it encounters a PROMPT-FOR statement, ABL designs the display of the prompt fields. When the procedure is run, the PROMPT-FOR statement puts data into those fields.

- If you are getting input from a device other than the terminal, and the number of characters read by the PROMPT-FOR statement for a particular field or variable exceeds the display format for that field or variable, the AVM returns an error. However, if you are setting a logical field that has a format of “y/n” and the data file contains a value of YES or NO, the AVM converts that value to “y” or “n”.

See also

DEFINE STREAM statement, EDITING phrase, Format phrase, Frame phrase, Stream object handle

PROMSGS function

Returns the current value of the ABL PROMSGS variable.

Syntax

PROMSGS

Example

This example uses the PROMSGS function to determine whether the default message file (promsgs) is in use. If not, it uses the PROMSGS function again to display the name of the current message file.

```
r-promsg.p

IF PROMSGS = "promsgs" THEN
  MESSAGE "Using default promsg file.".
ELSE
  MESSAGE "Using" PROMSGS.
```

See also

PROMSGS statement

PROMSGS statement

Sets the ABL PROMSGS variable for the current ABL session. The PROMSGS variable holds the name of the current ABL message file. ABL supplies different versions of this file to support various languages.

Syntax

```
PROMSGS = string-expression
```
string-expression

A character-string expression that resolves to the name of an ABL message file. You can specify a full or relative pathname for the messages file. Any relative pathname is relative to your current working directory.

Example

This example prompts the user for a language name and then tries to find a message file for that language. If the message file is found, then the PROMSGS statement is used to make that the current message file. Subsequently, all ABL system messages are read from the new promsgs file. The PROMSGS function is used in an informative message.

```
DEFINE VARIABLE newlang AS CHARACTER NO-UNDO FORMAT "x(16)"
   LABEL "Language".
DEFINE VARIABLE msgfile AS CHARACTER NO-UNDO.
SET newlang HELP "Enter the new language for messages.".
msgfile = IF newlang = "English" THEN "promsgs"
   ELSE "prolang/promsgs." + LC(SUBSTRING(newlang, 1, 3)).
IF SEARCH(msgfile) < > ? THEN DO:
   PROMSGS = msgfile.
   MESSAGE "Messages will now be taken from" PROMSGS.
   END.
ELSE DO:
   MESSAGE "Cannot find" msgfile.
   UNDO, RETRY.
END.
```

See also PROMSGS function

PROPATH function

Returns the current value of the PROPATH environment variable.

Syntax

```
PROPATH
```

Example

This procedure first displays a comma-separated list of the directories in the current PROPATH. It then displays each directory in the current PROPATH, one per line.

```
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DISPLAY PROPATH.
REPEAT ix = 1 TO NUM-ENTRIES(PROPATH):
   DISPLAY ENTRY(ix, PROPATH) FORMAT "x(30)".
END.
```

Notes

- ABL stores the PROPATH as a comma-separated list of directories. (ABL strips the operating-specific separation characters (a colon (:) on UNIX; a semicolon (;) in Windows) and replaces them with commas.)
• The default format for PROPATH is x(70).

• For more information on the PROPATH environment variable, see its reference entry in *OpenEdge Getting Started: Installation and Configuration*.

See also  PROPATH statement

### PROPATH statement

Sets the PROPATH environment variable for the current ABL session.

When you start ABL, it automatically adds the SDLC directory and some subdirectories to your PROPATH. ABL always preserves these directories in your PROPATH, even if you change or clear your PROPATH. Thus, ABL can always find its executables and r-code.

#### Syntax

```
PROPATH = string-expression
```

**string-expression**

A field, variable, string constant, or combination of these that evaluates to a character string. The character string should be a list of directory paths. The directory names in the path can be separated by commas or by the appropriate separation character for your operating system. The directory pathnames can use the UNIX format for pathnames (for example) or the standard pathname format for your operating system. Use the slash-separated directory name format if you are concerned about portability across multiple operating systems.

#### Examples

The *r-ppath.p* procedure displays a strip menu with four choices. The procedure defines three arrays: menu holds the items for selection on the menu, proglist holds the names of the programs associated with the menu selections, and ppath holds the appropriate PROPATHs for each program. The CHOOSE statement allows the user to choose an item from the strip menu.

**r-ppath.p**

```abl
DEFINE VARIABLE menu AS CHARACTER NO-UNDO EXTENT 4 FORMAT "X(20)"
DEFINE VARIABLE proglist AS CHARACTER NO-UNDO EXTENT 4 FORMAT "X(8)"
   INITIAL ["sales.p","acctg.p","per.p","exit.p"].
DEFINE VARIABLE ppath    AS CHARACTER NO-UNDO EXTENT 4
   INITIAL ["sales/s-procs","acctg/a-procs","per/p-procs",""].

REPEAT:
   DISPLAY menu WITH TITLE " M A I N   M E N U " CENTERED
      1 COLUMN 1 DOWN NO-LABELS ROW 8 ATTR-SPACE.
   CHOOSE FIELD menu AUTO-RETURN.
   HIDE.
   PROPATH = ppath[FRAME-INDEX].
   RUN VALUE(proglist[FRAME-INDEX]).
END.
```

The AVM uses the menu selection number as an index into the ppath and proglist arrays. The AVM sets the PROPATH and runs the program.

This simple example changes and displays the PROPATH:
Notes

- Changes to PROPATH last only for the current session. Any subprocesses inherit the PROPATH in effect when the ABL session started.

- When you start ABL, it automatically adds the top directory of the ABL hierarchy and some subdirectories to your PROPATH. If you use the PROPATH statement to make a change, ABL adds the directories you specify to your existing PROPATH.

- ABL replaces separation characters in expression (a colon (:) on UNIX; a semicolon (;) in Windows) with commas, so the resulting PROPATH string can be accessed with the ENTRY function. Therefore, file pathnames passed in expression must not include embedded commas.

- If you change your PROPATH, and your old PROPATH included r-code libraries that are not in your new PROPATH, those libraries are automatically closed. If you run a procedure from a closed library, the AVM displays an error message.

- For more information on the PROPATH environment variable, see *OpenEdge Getting Started: Installation and Configuration*.

See also ENTRY function, PROPATH function

### PROVERSION function

Returns the version of ABL, or release of OpenEdge, you are running.

**Note:** The PROVERSION function returns the version or release number as a character string. If you do not convert the returned character values to integer values (and strip off any letters) before sorting multiple return values, the values will not sort as expected. For example, the OpenEdge 10.0 release sorts before the Progress 9.1 version.

#### Syntax

```
PROVERSION
```

#### Example

The following example displays your current ABL version or OpenEdge release:

```
r-vers.p

MESSAGE "You are currently running Version/Release" PROVERSION.
```

#### Notes

- The PROVERSION function is not supported in Progress versions earlier than 7. If you want to test whether a procedure is running under an earlier version, you can use the KEYWORD function to determine whether PROVERSION is a keyword in that version. For example:
After you have determined that PROVERSION is available in the current version, then you can call a subroutine to invoke PROVERSION.

• For SpeedScript, this function returns the WebSpeed version.

See also: DBVERSION function, PROGRESS function

PUBLISH statement

Causes an ABL named event to occur.

Note: ABL named events are completely different from the key function, mouse, widget, and direct manipulation events described in the “Handle-based Object Events Reference” section on page 1827. They are also different from the class events described in the “Class Events Reference” section on page 1953.

Syntax:

```
PUBLISH event-name
  [ FROM publisher-handle ]
  [ ( parameter [ , parameter ] ... ) ]
```

`event-name`

A quoted character string or character expression representing the name of a named event. If you use a quoted character string, ABL adds `event-name` to the PUBLISHED-EVENTS attribute’s list of events.

`FROM publisher-handle`

A procedure or handle representing the procedure or widget to which ABL attributes the named event.

The FROM option lets a procedure publish an event on behalf of another procedure or widget. For example, if you want procedure A to publish a named event on behalf of procedure B, set `publisher-handle` to the procedure handle of B.

If the FROM option does not appear, ABL attributes the event to THIS-PROCEDURE, the procedure that contains the PUBLISH statement.

Note: If the FROM option does not appear and the PUBLISH statement occurs in a nonpersistent procedure that does not publicize its handle, potential subscribers have no way of knowing the handle’s value, and can subscribe to the event only by using the SUBSCRIBE statement’s ANYWHERE option.

```
( parameter [ , parameter ] ... )
```

The parameters, if any, of the named event.
PUBLISH statement

As in the RUN statement, you must supply a value for each INPUT and INPUT-OUTPUT parameter and a variable for each OUTPUT parameter.

Also, if a named event has one or more parameters, the PUBLISH statement and each subscriber’s local internal procedure (which the SUBSCRIBE statement names and which the AVM runs when the named event occurs) must specify identical signatures—where signature means the number of parameters and the data type and mode (INPUT, etc.) for each.

**Note:** When the named event occurs and the AVM runs each subscriber’s local internal procedure, if the signature of a local internal procedure does not match the signature in the PUBLISH statement, the AVM reports a run-time error. Since the PUBLISH statement runs with an implicit NO-ERROR, errors are stored in the ERROR-STATUS handle.

The parameter syntax is identical to that of the RUN statement. For its specification, see the Parameter passing syntax reference entry.

**Example**

The following example consists of four procedure files: a driver, a publisher, and two subscribers. The driver, *r-nedrvr.p*, runs the publisher and the two subscribers persistently, then subscribes to the event NewCustomer on behalf of the second subscriber.

**r-nedrvr.p**

```plaintext
/* r-nedrvr.p */
DEFINE VARIABLE hPub AS HANDLE NO-UNDO.
DEFINE VARIABLE hSub1 AS HANDLE NO-UNDO.
DEFINE VARIABLE hSub2 AS HANDLE NO-UNDO.

DEFINE BUTTON bNewCust LABEL "New Customer".
DEFINE BUTTON bQuit LABEL "Quit".

RUN r-nepub.p PERSISTENT SET hPub.
RUN r-nesub1.p PERSISTENT SET hSub1 (hPub).
RUN r-nesub2.p PERSISTENT SET hSub2.

/* Subscribe to event NewCustomer on behalf of subscriber 2 */
SUBSCRIBE PROCEDURE hSub2 TO "NewCustomer" IN hPub.

FORM bNewCust bQuit WITH FRAME x.
ENABLE ALL WITH FRAME x.
ONチョイス OF bNewCust RUN NewCust in hPub.
WAIT-FOR CHOICE OF bQuit OR WINDOW-CLOSE OF CURRENT-WINDOW.
```

The publisher, *r-nepub.p*, publishes the event NewCustomer:

**r-nepub.p**

```plaintext
/* r-nepub.p */
PROCEDURE NewCust:
    DEFINE VARIABLE name AS CHARACTER NO-UNDO INITIAL "Sam".

    /* Let subscriber know new customer */
    PUBLISH "NewCustomer" (INPUT name).
END PROCEDURE.
```
The first subscriber, nesub1.p, subscribes to the event NewCustomer:

**r-nesub1.p**

```plaintext
/* r-nesub1.p */
DEFINE INPUT PARAMETER hPub AS HANDLE NO-UNDO.
SUBSCRIBE TO "NewCustomer" IN hPub.

PROCEDURE NewCustomer:
    DEFINE INPUT PARAMETER name AS CHARACTER NO-UNDO.
    MESSAGE "Subscriber 1 received event NewCustomer concerning" name
    VIEW-AS ALERT-BOX.
END.
```

The second subscriber, nesub2.p, already subscribed to the event NewCustomer, cancels all subscriptions:

**r-nesub2.p**

```plaintext
/* r-nesub2.p */
PROCEDURE NewCustomer:
    DEFINE INPUT PARAMETER name AS CHARACTER NO-UNDO.
    MESSAGE "Subscriber 2 received event NewCustomer concerning" name
    VIEW-AS ALERT-BOX.
    /* This subscriber receives the first event, then removes itself */
    UNSUBSCRIBE TO ALL.
END.
```

To start the example, run the driver, r-nedrvr.p.

**Notes**

- If a named event has multiple subscribers, the order in which the AVM notifies subscribers is undefined.

- INPUT-OUTPUT parameters can accumulate values from a set of subscribers. When a subscriber receives an INPUT-OUTPUT parameter, it has the value that the previous subscriber set it to. When the publisher receives an INPUT-OUTPUT parameter, it has the value that the last subscriber set it to.

- If a named event with multiple subscribers has OUTPUT parameters, each time a subscriber sets an OUTPUT parameter, the AVM overwrites the previous value. For this reason, Progress Software Corporation recommends that you use OUTPUT parameters with named events only when there is a single subscriber.

- If a named event has multiple subscribers and several subscribers specify a RETURN statement with a return value, the RETURN-VALUE function evaluates to the return value set by the last subscriber.

- The AVM executes the PUBLISH statement with an implicit NO-ERROR option. To find out if any errors occurred, and if so, which ones, use the ERROR-STATUS system handle.
If `publisher-handle` is a handle, the value of SOURCE-PROCEDURE in each of the subscribers’ internal procedures will be the handle of the procedure that created the widget.

Publish( ) event method, PUBLISHED-EVENTS attribute, SUBSCRIBE statement, UNSUBSCRIBE statement

### PUT CURSOR statement  
(Characters only)

Makes the cursor visible on the screen at a specified position.

In data-handling statements such as UPDATE, SET, PROMPT-FOR, and INSERT, the AVM handles cursor display so the user knows where the cursor is located in the window. However, if data is entered through the READKEY statement, and that statement is not part of an EDITING phrase, you might want to turn the cursor on so the user can see the location of the cursor while entering data.

**Note:** Does not apply to SpeedScript programming.

#### Syntax

```plaintext
PUT CURSOR
{  OFF
      |  { [ ROW expression ] [ COLUMN expression ] }
}  
OFF
```

- **OFF**
  
  Ends display of the cursor.

- **ROW expression**
  
  The row in which you want to display the cursor. In the ROW option, `expression` is a constant, field name, variable name, or expression whose value is an integer that indicates the row where you want to display the cursor. If you do not use the ROW option, PUT CURSOR does not reposition the cursor. Similarly, if you specify a ROW that is outside the screen area, the AVM does not reposition the cursor.

- **COLUMN expression**
  
  The column in which you want to display the cursor. In the COLUMN option, `expression` is a constant, field name, variable name, or expression whose value is an integer that indicates the column where you want to display the cursor. If you do not use the COLUMN option, PUT CURSOR does not reposition the cursor. Similarly, if you specify a COLUMN that is outside the windows area, the AVM does not repositions the cursor.
Example

The following procedure uses PUT CURSOR to make the cursor visible in an editor window. When you run the procedure, you see a frame in a window. You can type text into this frame. The procedure reads each key you enter and takes the appropriate action. Then PUT CURSOR places the cursor in the first row and the first column in the editing frame when you first run the procedure. As you type, the cursor continues to be visible. As the procedure passes through the REPEAT loop for each keystroke, it takes action based on each keystroke and moves the cursor as it takes the action.

The procedure stores the information you type in the comments array, one character at a time. When you finish typing, press GO. The procedure displays the array where the AVM stored the typed information.

r-cursor.p

```plaintext
DEFINE VARIABLE comment AS CHARACTER NO-UNDO FORMAT "x(30)" EXTENT 4.
DEFINE VARIABLE iRow AS INTEGER NO-UNDO.
DEFINE VARIABLE iCol AS INTEGER NO-UNDO.
DEFINE VARIABLE lmargin AS INTEGER NO-UNDO INITIAL 5.
DEFINE VARIABLE rmargin AS INTEGER NO-UNDO INITIAL 34.
DEFINE VARIABLE ptop AS INTEGER NO-UNDO INITIAL 10.
DEFINE VARIABLE pbot AS INTEGER NO-UNDO INITIAL 13.
DEFINE VARIABLE r-ofst AS INTEGER NO-UNDO INITIAL 9.
DEFINE VARIABLE c-ofst AS INTEGER NO-UNDO INITIAL 4.

FORM SKIP(4) WITH WIDTH 32 ROW 9 COL 4 TITLE "Editor".
MESSAGE "Type text into the editor. Press" KLABEL("GO") "to end."
VIEW.

ASSIGN
  iRow = ptop
  iCol = lmargin.
```
Notes

- You must use the PUT SCREEN statement to display data when you use the PUT CURSOR statement. You also have to define a variable for the cursor position, and
increment it as the AVM reads the keys entered by the user if you want the cursor to move as the user types.

- The PUT CURSOR statement displays the cursor until you use the PUT CURSOR OFF statement to stop the display.
- Because a cursor is always displayed in an EDITING phrase, using the PUT CURSOR statement in an EDITING phrase (or if you have not issued a PUT CURSOR OFF statement before the phrase) might cause errors.

See also PUT SCREEN statement

PUT SCREEN statement
(Character only)

Displays a character expression at a specified location on a screen, overlaying any other data that might be displayed at that location.

This statement is supported only for backward compatibility.

Note: Does not apply to SpeedScript programming.

Syntax

```
PUT SCREEN
  [ ATTR-SPACE  | NO-ATTR-SPACE ]
  [ COLOR  color-phrase  ]
  [ COLUMN  expression  ]
  [ ROW  expression  ]
expression
```

ATTR-SPACE  | NO-ATTR-SPACE

Has no effect; supported only for backward compatibility.

COLOR  color-phrase

The video attributes you want to use to display an expression. When you display data in the first column of a spacetaking terminal, the AVM does not display that data with color. If you are displaying data in a column other than column 1, the AVM displays the color attribute in the column prior to the current column (current column minus 1).
PUT SCREEN statement

COLUMN expression

The column in which you want to display an expression. In the COLUMN option, expression is a constant, field name, variable name, or expression whose value is an integer that indicates the column in which you want to display an expression. If you do not use the COLUMN option, PUT SCREEN displays the expression at column 1. If you specify a COLUMN that is outside the screen area, the AVM disregards the PUT SCREEN statement.

ROW expression

The row in which you want to display an expression. In the ROW option, expression is a constant, field name, variable name, or expression whose value is an integer that indicates the row you want to display an expression. If you do not use the ROW option, PUT SCREEN displays the expression at row 1. If you specify a ROW that is outside the screen area, the AVM disregards the PUT SCREEN statement.

expression

A constant, field name, variable name, or expression that results in a character string. The character string can contain control characters and can be as long as you want.

Example The r-putscr. procedure determines whether a Customer’s current balance is above or below 0. If it is above 0, they have a credit; if it is below 0, they owe money. The label of the balance column is changed based on whether they have a credit or owe money.

For more information, see the COLOR phrase reference entry.
PUT statement

Sends the value of one or more expressions to an output destination other than the terminal.

```
DEFINE VARIABLE paid-owed AS DECIMAL NO-UNDO.
DEFINE VARIABLE bal-label AS CHARACTER NO-UNDO FORMAT "x(20)".

FOR EACH Customer NO-LOCK:
  IF paid-owed < 0 /* Customer has a credit */ THEN DO:
    paid-owed = - paid-owed.
    bal-label = "Customer Credit".
  END.
  ELSE bal-label = "Unpaid balance".
  DISPLAY Customer.CustNum Customer.Name paid-owed LABEL " " WITH 1 DOWN.
  IF Customer.Balance < 0 THEN
    PUT SCREEN COLOR MESSAGES ROW 2 COLUMN 34 bal-label.
  ELSE
    PUT SCREEN ROW 2 COLUMN 34 bal-label.
  END.
```

If the Customer has a credit (balance < 0) the first PUT SCREEN statement displays the value of bal-label (which is Customer Credit) in the same color as you see system MESSAGES (usually reverse video).

If the Customer owes money (balance > 0) the second PUT SCREEN statement displays the value of bal-label (which is Current Balance) in normal display mode.

Notes

- Values displayed by PUT SCREEN are not the same as values that belong to frames. Thus those expressions can be overwritten by other displays or hides. Ensure that values displayed by PUT SCREEN do not overwrite frame fields that are used later for data entry.

- If you use the PUT SCREEN statement in a procedure that runs in batch or background mode, the AVM disregards the PUT SCREEN statement.

- The HIDE ALL statement clears the entire screen, including any data displayed by a PUT SCREEN statement.

- The Wyse 75 terminal is spacetaking for some COLOR attributes and non-spacetaking for others. This difference interferes with resetting COLOR MESSAGE (non-spacetaking) back to COLOR NORMAL in a PUT SCREEN statement. If you use WHITE instead of NORMAL whenever you reset color attributes back to normal video attributes, the Wyse 75 behaves like other terminals.

- If you use the PUT SCREEN statement to display data in the message area, the HIDE MESSAGES statement does not necessarily clear that data.

See also COLOR phrase, DISPLAY statement, HIDE statement, PUT statement
PUT statement

Syntax

```
PUT [ STREAM stream | STREAM-HANDLE handle ]
 [ UNFORMATTED ]
 [ { expression
   [ FORMAT string ]
   [ { AT | TO } expression ]
  } ]
 [ SKIP [ ( expression ) ]
 [ SPACE [ ( expression ) ] ]
 ] ...

PUT [ STREAM stream | STREAM-HANDLE handle ] CONTROL expression ...
```

STREAM name

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream. See the DEFINE STREAM statement reference entry and chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams.

STREAM-HANDLE handle

Specifies the handle to a stream. If handle it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams and stream handles.

UNFORMATTED

Tells the AVM to display each expression in the same format produced by the EXPORT statement, but without quotes.

expression

Specifies a constant, field name, variable name, or expression.

FORMAT string

The format in which you want to display the expression. If you do not use the FORMAT option, the AVM uses the defaults shown in Table 56.

### Table 56: Default display formats

<table>
<thead>
<tr>
<th>Type of expression</th>
<th>Default format</th>
</tr>
</thead>
<tbody>
<tr>
<td>Field</td>
<td>Format from Dictionary</td>
</tr>
<tr>
<td>Variable</td>

<tbody>
<tr>
<td>Constant character</td>
<td>Length of character string</td>
</tr>
<tr>
<td>Other</td>
<td>Default format for the data type of the expression</td>
</tr>
</tbody>
</table>

Table 57 shows the default formats for other expressions.

Table 57: Default data type display formats

<table>
<thead>
<tr>
<th>Data type</th>
<th>Default display format</th>
</tr>
</thead>
<tbody>
<tr>
<td>CHARACTER</td>
<td>x(8)</td>
</tr>
<tr>
<td>CLASS&lt;sup&gt;3&lt;/sup&gt;</td>
<td>&gt;&gt;&gt;&gt;&gt;&gt;&gt;9</td>
</tr>
<tr>
<td>DATE</td>
<td>99/99/99</td>
</tr>
<tr>
<td>DATETIME</td>
<td>99/99/9999 HH:MM:SS.SSS</td>
</tr>
<tr>
<td>DECIMAL</td>
<td>-&gt;&gt;&gt;,&gt;&gt;9.99</td>
</tr>
<tr>
<td>HANDLE&lt;sup&gt;2&lt;/sup&gt;</td>
<td>&gt;&gt;&gt;&gt;&gt;&gt;&gt;9</td>
</tr>
<tr>
<td>INT64</td>
<td>-&gt;&gt;&gt;,&gt;&gt;,9</td>
</tr>
<tr>
<td>INTEGER</td>
<td>-&gt;&gt;&gt;,&gt;&gt;,9</td>
</tr>
<tr>
<td>LOGICAL</td>
<td>yes/no</td>

<tr>
<td>MEMPTR&lt;sup&gt;1&lt;/sup&gt;</td>
<td>See the note at the end of the table.</td>
</tr>
<tr>
<td>RAW&lt;sup&gt;1&lt;/sup&gt;</td>
<td>See the note at the end of the table.</td>
</tr>
<tr>
<td>RECID</td>
<td>&gt;&gt;&gt;&gt;&gt;&gt;&gt;9</td>
</tr>
<tr>
<td>ROWID&lt;sup&gt;1&lt;/sup&gt;</td>
<td>See the note at the end of the table.</td>
</tr>
</tbody>
</table>

1 You cannot display a MEMPTR, RAW, or ROWID value directly. However, you can convert it to a character string representation using the STRING function and display the result. A ROWID value converts to a hexadecimal string, “0x<sup>hexdigits</sup>,” where <sup>hexdigits</sup> is any number of characters “0” through “9” and “A” through “F”. A MEMPTR or RAW value converts to decimal integer string.

2 To display a HANDLE, you must first convert it using either the INT64 or INTEGER function and display the result.

3 To display a CLASS, you must first convert it using the INT64, INTEGER, or STRING function and display the result.

**AT expression**

Specifies the column position where you want to place the output value. If that position has already been used on the current line, PUT skips to the next line and puts the expression in the specified column.
**PUT statement**

**TO** *expression*

Specifies the column position where you want to end the output value being output. If that position has already been used on the current line, PUT skips to the next line and puts the *expression* in the specified column.

**SKIP** [( *expression*)]

Specifies the number of new lines you want to output. If you do not use the SKIP option, PUT will not start a new line to the output stream. If you use the SKIP parameter, but do not specify *expression* (or if *expression* is 0), the AVM starts a new line only if output is not already positioned at the beginning of a new line.

**SPACE** [( *expression*)]

Specifies the number of spaces you want to output. Spaces are not placed between items being PUT unless you use the SPACE option.

**CONTROL** *expression*

The expression specifies a control sequence that you want to send without affecting the current line, page counters, and positions maintained within ABL. Following CONTROL, *expression* can be a character-string expression or a RAW variable. It can include null character constants of the form NULL or NULL( *expression*), where *expression* specifies the number of NULLs to send. See the Notes section in this reference entry for details.

**Example**

This procedure creates a text file that contains the names of each customer. The names are separated from each other by a slash (/). The entire file consists of one long line.

```
DEFINE STREAM s1.
 OUTPUT STREAM s1 TO cus.dat.
 FOR EACH Customer NO-LOCK:
   PUT STREAM s1 name "/".
 END.
 OUTPUT STREAM s1 CLOSE.
```

**Notes**

- In the AT, TO, SKIP, and SPACE options, if *expression* is less than or equal to 0, the AVM disregards the option.

- The PUT statement never automatically starts a new line. You must use SKIP to explicitly start a new line.

- The PUT statement uses the default display format for the data type of the field or variable you name in the PUT statement. The PUT statement does not overwrite an area that is already used by a previous format when it displays data. For example:
PUT-BITS statement

Use the UNFORMATTED option with the PUT statement to override the format-sensitive display.

• You can use the NULL keyword to output null characters (\0) in a control sequence. For example, the following statements write the control sequence \0 and 20 NULLs to output stream A:

```plaintext
PUT STREAM A CONTROL "~033A" NULL.
PUT STREAM A CONTROL NULL(20).
```

• You can use the PUT statement with an object reference for a class instance. The PUT statement implicitly calls the ToString( ) method of the class to convert the specified object reference to a character value before it sends the value to the output destination.

See also DEFINE STREAM statement, DISPLAY statement, EXPORT statement, OUTPUT TO statement, PAGE statement, PUT SCREEN statement, Stream object handle

PUT-BITS statement

Uses the bit representation of an integer to set a given number of bits at a given location within another integer.

Syntax

PUT-BITS( destination , position , numbites ) = expression

destination

An ABL integer variable. The statement sets bits in destination that correspond to the bits that are on in the source variable, expression. It clears bits in the destination variable that are 0 in the source variable. Note that the number of bits set or cleared is limited by the numbites parameter, and the location within the destination is determined by the position variable.
PUT-BYTE statement

**position**

A variable or expression that returns an integer. This parameter designates the position of the lowest-order bit of the bits that are to be interpreted as an integer. Bits are numbered from 1 through the length of an integer; with 1 being the low-order bit. If `position` is greater than the length of an integer or less than 1, the AVM generates a run-time error.

**numbits**

The number of bits to examine when generating the return value. If `position` plus `numbits` is greater than the length of an integer plus 1, the AVM generates a run-time error.

**expression**

A source variable that returns an integer. If the integer cannot be represented in the number of bits specified by `numbits`, the AVM stores the low-order `numbits` bits of the integer.

See also

GET-BITS function

**PUT-BYTE statement**

Stores the unsigned 1-byte value of an integer expression at the specified memory location.

**Syntax**

```
PUT-BYTE ( destination, position ) = expression
```

**destination**

A variable of type RAW or MEMPTR. If `destination` is the Unknown value (?), it remains the Unknown value (?). If `destination` is a MEMPTR and has not had its region allocated (by a SET-SIZE statement or by a Windows dynamic link library (DLL) or UNIX shared library routine), the AVM generates a run-time error.

**position**

An integer value greater than 0 that indicates the byte position where the AVM stores `expression`. If `position` is less than 1, the AVM generates a run-time error. For a RAW `destination`, if `position` is greater than the length of `destination`, the AVM changes the length of `destination` to `position` and pads the gap with null bytes. For a MEMPTR `destination`, if `position` is greater than the length of `destination`, the AVM generates a run-time error.

**expression**

The integer value of a constant, field, variable, function, or expression. If `expression` is less than 0 or greater than 255, the AVM stores the right-most byte value of `expression` in `destination`.

**Examples**

This procedure finds the name of Customer 26, Jack’s Jacks, and stores it in the RAW variable `r1`. The PUT-BYTE statement replaces the first four bytes in the `Name` with the specified character code values. The procedure then writes the values in `r1` back into the `Name` field and displays that field. Jack’s Jacks becomes Bill’s Jacks.
The following example allocates a MEMPTR region large enough to hold the character string “Bill”, terminated by a null byte. It stores the string one byte at a time using the PUT-BYTE statement, and then displays the string directly from the region.

```plaintext
/* You must connect to a non-OpenEdge demo database to run this procedure */
DEFINE VARIABLE r1 AS RAW NO-UNDO.
DISPLAY Customer.Name.
ASSIGN
  r1 = RAW(Customer.Name)
  PUT-BYTE(r1,1) = ASC('B')
  PUT-BYTE(r1,2) = ASC('i')
  PUT-BYTE(r1,3) = ASC('l')
  PUT-BYTE(r1,4) = ASC('l')
  RAW(Customer.Name) = r1.
DISPLAY Customer.Name.
```

The following example allocates a MEMPTR region large enough to hold the character string “Bill”, terminated by a null byte. It stores the string one byte at a time using the PUT-BYTE statement, and then displays the string directly from the region.

```plaintext
DEFINE VARIABLE mptr AS MEMPTR NO-UNDO.
ASSIGN
  SET-SIZE(mptr) = LENGTH("Bill") + 1
  PUT-BYTE(mptr,1) = ASC('B')
  PUT-BYTE(mptr,2) = ASC('i')
  PUT-BYTE(mptr,3) = ASC('l')
  PUT-BYTE(mptr,4) = ASC('l')
  PUT-BYTE(mptr,5) = 0.
DISPLAY GET-STRING(mptr,1).
```

**Note**
For more information on accessing DLL routines from ABL, see *OpenEdge Development: Programming Interfaces*.

**See also**
GET-BYTE function, LENGTH function, LENGTH statement, RAW function, RAW statement, SET-SIZE statement

**PUT-BYTES statement**
Copies a RAW or MEMPTR variable to the specified location in another RAW or MEMPTR variable.

**Syntax**
```
PUT-BYTES ( destination, position ) = expression
```

**destination**
An expression that returns a target RAW or MEMPTR variable. If destination is the Unknown value (?), PUT-BYTES does nothing.
PUT-DOUBLE statement

position

An integer value greater than 0 that indicates the byte position where you want to put the data. If position is less than 1, the AVM generates a run-time error.

For a RAW variable, if position is greater than the length of destination, the AVM increases the length of destination to position plus the remaining bytes needed to store expression. The gap between the original destination length and position is padded with null bytes.

For a MEMPTR variable, if position is greater than the length of destination or does not leave sufficient room to store expression, the AVM generates a run-time error. If destination is a RAW and position plus the length of expression is greater than 32K, the AVM generates a run-time error.

expression

An expression that returns a RAW or MEMPTR variable.

See also

GET-BYTES function, LENGTH function, LENGTH statement, RAW function, RAW statement, SET-SIZE statement

PUT-DOUBLE statement

Stores the 8-byte floating-point value of a DECIMAL expression at the specified memory location.

Syntax

```
PUT-DOUBLE ( destination , position ) = expression
```

destination

A variable of type RAW or MEMPTR. If destination is the Unknown value (?), it remains the Unknown value (?). If destination is a MEMPTR and has not had its region allocated (by a SET-SIZE statement or by a Windows dynamic link library (DLL) or UNIX shared library routine), the AVM generates a run-time error.

position

An integer value greater than 0 that indicates the byte position where the AVM stores expression. If position is less than 1, the AVM generates a run-time error.

For a RAW destination, if position is greater than the length of destination, the AVM increases the length of destination to position plus the remaining bytes needed to store expression. The gap between the original destination length and position is padded with null bytes.

For a MEMPTR destination, if position is greater than the length of destination or does not leave sufficient room to store expression, the AVM generates a run-time error.

expression

The DECIMAL value of a constant, field, variable, function, or expression.
PUT-FLOAT statement

Stores the 4-byte floating-point value of a DECIMAL expression at the specified memory location.

Syntax

```
PUT-FLOAT ( destination , position ) = expression
```

**destination**

A variable of type RAW or MEMPTR. If `destination` is the Unknown value (?), it remains the Unknown value (?). If `destination` is a MEMPTR and has not had its region allocated (by a SET-SIZE statement or by a Windows dynamic link library (DLL) or UNIX shared library routine), the AVM generates a run-time error.

**position**

An integer value greater than 0 that indicates the byte position where the AVM stores `expression`. If `position` is less than 1, the AVM generates a run-time error.

For a RAW `destination`, if `position` is greater than the length of `destination`, the AVM increases the length of `destination` to `position` plus the remaining bytes needed to store `expression`. The gap between the original `destination` length and `position` is padded with null bytes.

For a MEMPTR `destination`, if `position` is greater than the length of `destination` or does not leave sufficient room to store `expression`, the AVM generates a run-time error.

**expression**

The DECIMAL value of a constant, field, variable, function, or expression.

**Example**

For examples of how to use the PUT-FLOAT statement, see the PUT-BYTE statement reference entry.

**Notes**

- This statement supports byte-swapping only if `destination` is a MEMPTR data type. The statement will first examine the byte-order setting of the MEMPTR and then swap the bytes appropriately while putting the data into the MEMPTR memory.
PUT-INT64 statement

Stores the signed 64-bit value of an INT64 or INTEGER expression at the specified memory location as an INT64 data type.

Syntax

```
PUT-INT64 ( destination , position ) = expression
```

**destination**

A variable of type RAW or MEMPTR. If destination is the Unknown value (?), it remains the Unknown value (?). If destination is a MEMPTR and its region in not allocated (by a SET-SIZE statement or by a Windows dynamic link library (DLL) or UNIX shared library routine), the AVM generates a run-time error.

**position**

An integer value greater than 0 that indicates the byte position where the AVM stores expression. If position is less than 1, the AVM generates a run-time error.

For a RAW destination, if position is greater than the length of destination, the AVM increases the length of destination to position plus the remaining bytes needed to store expression. The gap between the original destination length and position is padded with null bytes.

For a MEMPTR destination, if position is greater than the length of destination or does not leave sufficient room to store expression, the AVM generates a run-time error.

**expression**

The integer value of a constant, field, variable, function, or expression.

**Example**

See the example in the GET-INT64 function section.

**See also**

GET-INT64 function, INT64 function, PUT-LONG statement

---

PUT-KEY-VALUE statement

(Windows only)

Adds, modifies, and deletes keys in the current environment.

**Note:** Does not apply to SpeedScript programming.
PUT-KEY-VALUE statement

Syntax

```plaintext
PUT-KEY-VALUE
{ { SECTION section-name
   KEY { key-name | DEFAULT }
   VALUE value
   }
| { COLOR | FONT } { number | ALL }
} [ NO-ERROR ]
```

**SECTION section-name**

A CHARACTER expression that specifies the name of the section that contains the key of interest.

In initialization files, section names appear in square brackets([]). When you specify a section name in a PUT-KEY-VALUE statement, omit the square brackets.

**KEY key-name**

A CHARACTER expression that specifies the name of the key of interest.

**DEFAULT**

Tells PUT-KEY-VALUE to use the default key of section section-name.

Some applications store data in the registry under the default key of a section. This option lets you modify this data. For an example, see the EXAMPLES section of this entry.

This option applies only to the registry and not to initialization files.

**VALUE value**

The value of the key to write to the environment. value must evaluate to a CHARACTER expression of no more than 128 bytes.

**COLOR { number | ALL }**

Updates color definitions in the current environment from the definitions in the internal color table. The number parameter is a literal integer that specifies the number of a single color in the current environment whose definition you want to update. The ALL option updates all color definitions in the current environment.

**FONT { number | ALL }**

Updates font definitions in the current environment from the definitions in the internal font table. The number parameter is a literal integer that specifies the number of a single font in the current environment whose definition you want to update. The ALL option updates all font definitions in the current environment.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that
PUT-KEY-VALUE statement

contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

**Examples**

If the current environment resides in the registry, the PUT-KEY-VALUE statement:

1. Searches in the registry under the current environment for the subkey MYSECTION
2. Creates MYSECTION if it does not exist
3. Searches MYSECTION for the subkey MYKEY
4. Sets MYKEY to the value MYVARIABLE (if MYKEY exists),
or adds MYKEY and the value MYVARIABLE (if MYKEY does not exist)

If the current environment resides in an initialization file, the PUT-KEY-VALUE statement:
1. Searches the initialization file for the section MYSECTION
2. Creates MYSECTION if it does not exist
3. Searches MYSECTION for the key MYKEY
4. Sets MYKEY to the value MYVARIABLE (if MYKEY exists),
or adds MYKEY and the value MYVARIABLE (if MYKEY does not exist):

```
PUT-KEY-VALUE SECTION "MYSECTION" KEY "MYKEY" VALUE MYVARIABLE
```

If the current environment resides in the registry, the following examples add, directly under the
current environment, the value name MYKEY and the value MYVARIABLE:

```
PUT-KEY-VALUE SECTION "" KEY "MYKEY" VALUE MYVARIABLE

PUT-KEY-VALUE SECTION "?" KEY "MYKEY" VALUE MYVARIABLE
```

If the current environment resides in an initialization file, the previous examples return an error.

If the current environment resides in the registry, the following examples:
1. Search in the registry under the current environment for the key MYSECTION.
2. Search MYSECTION for the value name MYKEY.
3. Delete MYKEY and its value.

```
PUT-KEY-VALUE SECTION "MYSECTION" KEY "MYKEY" VALUE ""

PUT-KEY-VALUE SECTION "MYSECTION" KEY "MYKEY" VALUE ?
```

If the current environment resides in an initialization file, the previous examples delete the key
MYKEY, including its value, from the section MYSECTION.

If the current environment resides in the registry, the following examples delete the subkey
MYSECTION, all values under MYSECTION, all subkeys under MYSECTION, and all values
under those subkeys:

```
PUT-KEY-VALUE SECTION "MYSECTION " KEY "?" VALUE ?
```
If the current environment resides in an initialization file, the previous examples remove the section MYSECTION, and all key-value pairs within MYSECTION, from the initialization file.

If the current environment resides in the registry, the following example:

1. Searches the current environment for the subkey MYAPP
2. Sets the default key under MYAPP to NEWVALUE

If the current environment resides in an initialization file, the previous example returns an error.

**Notes**

- Environments typically consist of sections, each of which contains keys, each of which consists of a name and a value. A typical section name is COLORS. A typical key within this section consists of the name COLOR7 and the value 255,255,0. This key attaches the name COLOR7 to color value 255,255,0 (a color specification that uses the red-green-blue color-naming scheme).

The current environment might be the registry or an initialization file. The registry consists of sections called keys and subkeys arranged in a hierarchy. Keys and subkeys contain value entries, each of which consists of a value name and value data. Initialization files, by contrast, consist of a single level of sections. Sections contain entries, each of which consists of a name, an equal sign (=), and a value.

For more information on environments, see the chapter on colors and fonts in *OpenEdge Development: Programming Interfaces*.

- The current environment is one of the following:
  - The default environment
  - An environment that a startup parameter specified (the *startup environment*)
  - An environment that a LOAD statement loaded and that the most recent USE statement made current

- If you UNLOAD the current environment, a subsequent PUT-KEY-VALUE writes to the startup environment.

- To remove a key-value pair from an environment, set *key-name* to the name of the key and *value* to the Unknown value (?).

- To remove a section, including all its key-value pairs, from an environment, set *section-name* to the name of the section and *key-name* to the Unknown value (?).

- To change the definitions in the internal color table, use one of the following techniques:
  - To display a dialog box that lets the user change the color definitions, use the SYSTEM-DIALOG-COLOR statement.
– To change the color definitions directly from ABL, use the attributes and methods of the COLOR-TABLE handle.

**Note:** The COLOR option of the PUT-KEY-VALUE statement does not change the definitions in the internal color table. This option merely moves some or all of those definitions to the current environment.

• To change the definitions in the internal font table, use one of the following techniques:
  – To display a dialog box that lets the user change the font definitions, use the SYSTEM-DIALOG-FONT statement.
  – To change the font definitions directly from ABL, use the attributes and methods of the FONT-TABLE handle.

**Note:** The FONT option of the PUT-KEY-VALUE statement does not change the definitions in the internal font table. This option merely moves some or all of those definitions to the current environment.

• For more information on colors and fonts, see the chapter on colors and fonts in *OpenEdge Development: Programming Interfaces*.

COLOR-TABLE system handle, FONT-TABLE system handle, GET-KEY-VALUE statement, LOAD statement, SYSTEM-DIALOG COLOR statement, SYSTEM-DIALOG FONT statement, UNLOAD statement, USE statement

---

**PUT-LONG statement**

Stores the signed 32-bit value of an integer expression at the specified memory location.

**Syntax**

```plaintext
PUT-LONG (destination, position) = expression
```

**destination**

A variable of type RAW or MEMPTR. If `destination` is the Unknown value (?), it remains the Unknown value (?). If `destination` is a MEMPTR and its region in not allocated (by a SET-SIZE statement or by a Windows dynamic link library (DLL) or UNIX shared library routine), the AVM generates a run-time error.

**position**

An integer value greater than 0 that indicates the byte position where the AVM stores `expression`. If `position` is less than 1, the AVM generates a run-time error.

For a RAW `destination`, if `position` is greater than the length of `destination`, the AVM increases the length of `destination to position` plus the remaining bytes needed to store `expression`. The gap between the original `destination` length and `position` is padded with null bytes.
PUT-SHORT statement

For a MEMPTR destination, if position is greater than the length of destination or does not leave sufficient room to store expression, the AVM generates a run-time error.

expression

The integer value of a constant, field, variable, function, or expression.

Notes

• For examples of how to use the PUT-LONG statement, see the PUT-BYTE statement reference entry.

• This statement supports byte-swapping only if destination is a MEMPTR data type. The statement will first examine the byte-order setting of the MEMPTR and then swap the bytes appropriately while putting the data into the MEMPTR memory.

• For more information on accessing DLL routines from ABL, see OpenEdge Development: Programming Interfaces.

See also GET-LONG function, LENGTH function, LENGTH statement, RAW function, RAW statement, SET-SIZE statement

PUT-SHORT statement

Stores the signed 16-bit value of an integer expression at the specified memory location.

Syntax

PUT-SHORT ( destination, position ) = expression

destination

A variable of type RAW or MEMPTR. If destination is the Unknown value (?), it remains the Unknown value (?). If destination is a MEMPTR and its region is not allocated (by a SET-SIZE statement or by a Windows dynamic link library (DLL) or UNIX shared library routine), the AVM generates a run-time error.

position

An integer value greater than 0 that indicates the byte position where the AVM stores expression. If position is less than 1, the AVM generates a run-time error.

For a RAW destination, if position is greater than the length of destination, the AVM increases the length of destination to position plus the remaining bytes needed to store expression. The gap between the original destination length and position is padded with null bytes.

For a MEMPTR destination, if position is greater than the length of destination or does not leave sufficient room to store expression, the AVM generates a run-time error.

expression

The integer value of a constant, field, variable, function, or expression.

Notes

• For examples of how to use the PUT-SHORT statement, see the PUT-BYTE statement reference entry.
• This statement supports byte-swapping only if destination is a MEMPTR data type. The statement will first examine the byte-order setting of the MEMPTR and then swap the bytes appropriately while putting the data into the MEMPTR memory.

• For more information on accessing DLL routines from ABL, see *OpenEdge Development: Programming Interfaces*.

See also  
GET-SHORT function, LENGTH function, LENGTH statement, RAW function, RAW statement, SET-SIZE statement

---

**PUT-STRING statement**

Stores the null-terminated value of a CHARACTER or LONGCHAR expression at the specified memory location. If numbytes is specified, PUT-STRING will copy the requested number of bytes from the variable, regardless of whether there are embedded nulls. In this case PUT-STRING will not put a terminating null into the MEMPTR unless the last byte copied happens to be a null.

**Syntax**

```
PUT-STRING ( destination, position, [ numbytes ] ) = expression
```

**destination**

A variable of type RAW or MEMPTR. If destination is the Unknown value (?), it remains the Unknown value (?). If destination is a MEMPTR and its region is not allocated (by a SET-SIZE statement or by a Windows dynamic link library (DLL) or UNIX shared library routine), the AVM generates a run-time error.

**position**

An integer value greater than 0 that indicates the byte position where the AVM stores expression. If position is less than 1, the AVM generates a run-time error.

For a RAW destination, if position is greater than the length of destination, the AVM increases the length of destination to position plus the remaining bytes needed to store expression. The gap between the original destination length and position is padded with null bytes.

For a MEMPTR destination, if position is greater than the length of destination or does not leave sufficient room to store expression, the AVM generates a run-time error.

**numbytes**

An integer value greater than 0 that indicates how many bytes to copy from expression. If position plus numbytes is greater than the length of destination, the AVM generates a run-time error.

**expression**

An expression (a constant, field name, variable name, or expression) whose value is a CHARACTER or LONGCHAR. The AVM converts a LONGCHAR value to -cpinternal before it stores the value.
PUT-UNSIGNED-LONG statement

Notes

- For examples of how to use the PUT-STRING statement, see the PUT-BYTE statement reference entry.
- For more information on accessing DLL and UNIX shared library routines from ABL, see *OpenEdge Development: Programming Interfaces*.

See also

GET-STRING function, LENGTH function, LENGTH statement, RAW function, RAW statement, SET-SIZE statement

**PUT-UNSIGNED-LONG statement**

Writes an INTEGER or INT64 value as a 32-bit unsigned value to a MEMPTR or RAW value. This statement is analogous to the PUT-UNSIGNED-SHORT statement, except with a 32-bit value.

**Syntax**

```plaintext
PUT-UNSIGNED-LONG (destination, position) = expression
```

*destination*

A MEMPTR or RAW variable. If `destination` is the Unknown value (?), it remains the Unknown value (?). If `destination` is a MEMPTR and its region is not allocated (by a SET-SIZE statement, or by a Windows DLL or Unix shared object entry point), the AVM generates a run-time error.

*position*

An INTEGER or INT64 value greater than 0 that indicates the byte position to write `expression`. If `position` is less than 1, the AVM generates a run-time error. For a RAW `destination`, if `position` is greater than the length of `destination`, the AVM increases the length of `destination to position` plus the remaining bytes needed to store `expression`. The gap between the original `destination` length and `position` is padded with null bytes. For a MEMPTR `destination`, if `position` is greater than the length of `destination` or does not leave sufficient room to store `expression`, the AVM generates a run-time error.

For a RAW `destination`, if `position` is greater than the length of `destination`, the AVM increases the length of `destination` to `position` plus the remaining bytes needed to store `expression`. The gap between the original `destination` length and `position` is padded with null bytes.

For a MEMPTR `destination`, if `position` is greater than the length of `destination` or does not leave sufficient room to store `expression`, the AVM generates a run-time error.

*expression*

An INTEGER or INT64 value of a constant, field, variable or expression. If `expression` is an INT64 value exceeding the maximum value of an UNSIGNED-LONG, the AVM generate an overflow error at run time.

**Notes**

- This statement supports byte-swapping only if `destination` is a MEMPTR data type. The statement will first examine the byte-order setting of the MEMPTR and then swap the bytes appropriately while putting the data into the MEMPTR memory.
PUT-UNSIGNED-SHORT statement

Stores the unsigned 16-bit value of an integer expression at the specified memory location.

Syntax

\[
\text{PUT-UNSIGNED-SHORT ( \text{destination} , \text{position} ) = \text{expression}}
\]

**destination**

A variable of type RAW or MEMPTR. If \textit{destination} is the Unknown value (?), it remains the Unknown value (?). If \textit{destination} is a MEMPTR and its region is not allocated (by a SET-SIZE statement or by a Windows dynamic link library (DLL) or UNIX shared library routine), the AVM generates a run-time error.

**position**

An integer value greater than 0 that indicates the byte position where the AVM stores \textit{expression}. If \textit{position} is less than 1, the AVM generates a run-time error.

For a RAW \textit{destination}, if \textit{position} is greater than the length of \textit{destination}, the AVM increases the length of \textit{destination} to \textit{position} plus the remaining bytes needed to store \textit{expression}. The gap between the original \textit{destination} length and \textit{position} is padded with null bytes.

For a MEMPTR \textit{destination}, if \textit{position} is greater than the length of \textit{destination} or does not leave sufficient room to store \textit{expression}, the AVM generates a run-time error.

**expression**

The integer value of a constant, field, variable, function, or expression.

**Notes**

- This statement supports byte-swapping only if \textit{destination} is a MEMPTR data type. The statement will first examine the byte-order setting of the MEMPTR and then swap the bytes appropriately while putting the data into the MEMPTR memory.

- For more information on accessing DLL routines from ABL, see \textit{OpenEdge Development: Programming Interfaces}.

GET-UNSIGNED-SHORT function, LENGTH function, LENGTH statement, RAW function, RAW statement, SET-SIZE statement

QUERY-OFF-END function

Returns a LOGICAL value indicating whether the specified query is positioned at the end of its result list (either before the first record or after the last record).
QUERY-OFF-END (query-name)

**query-name**

A character expression that evaluates to the name of a currently open query. If `query-name` does not resolve to the name of a query, or if the query is not open, then the function returns the Unknown value (\?).

**Note:** Searching for a query using a handle is more efficient than a character expression. The AVM resolves a character expression at run time by searching in the current routine for a static query with that name. If not found, the AVM searches the enclosing main procedure. If still not found, the AVM searches up through the calling programs of the current routine, and their main procedures. Since a handle uniquely identifies a query, no such search is required. Use the query object handle’s **QUERY-OFF-END attribute** to avoid a run-time search.

**Example**
The following example uses the QUERY-OFF-END function to determine when to leave the REPEAT loop:

```r-qoff.p
OPEN QUERY cust-query FOR EACH Customer.
REPEAT:
   GET NEXT cust-query.
   IF QUERY-OFF-END("cust-query") THEN LEAVE.
END.
```

When you run this procedure, all Customer numbers and names are displayed. After the last record is displayed, the loop iterates and the GET NEXT statement reads beyond the last record. At this point QUERY-OFF-END returns TRUE and the AVM exits the loop.

**Note**
To test whether a GET statement read beyond the last (or first) record, you can use the AVAILABLE function with the buffer name. You can also use the QUERY-OFF-END function, which serves the same purpose, but does not require a specific buffer; it requires only a query name.

**See also**
CLOSE QUERY statement, CURRENT-RESULT-ROW function, DEFINE BROWSE statement, DEFINE QUERY statement, GET statement, NUM-RESULTS function, OPEN QUERY statement, QUERY-OFF-END attribute, REPOSITION statement

**QUERY-TUNING phrase**

Allows programmatic control over the execution of a query in a DataServer application. This phrase is available for the DataServers; it is not available for queries of OpenEdge databases.
Syntax

```sql
QUERY-TUNING
(
  ARRAY-MESSAGE | NO-ARRAY-MESSAGE
  BIND-WHERE | NO-BIND-WHERE
  CACHE-SIZE integer
  DEBUG { SQL | EXTENDED diag-option } | NO-DEBUG
  INDEX-HINT | NO-INDEX-HINT
  JOIN-BY-SQLDB | NO-JOIN-BY-SQLDB
  LOOKAHEAD | NO-LOOKAHEAD
  ORDERED-JOIN
  REVERSE-FROM
  SEPARATE-CONNECTION | NO-SEPARATE-CONNECTION
)
```

The following descriptions are general. For more detailed information, see the OpenEdge DataServer Guides (OpenEdge Data Management: DataServer for Microsoft SQL Server, OpenEdge Data Management: DataServer for ODBC, and OpenEdge Data Management: DataServer for Oracle).

**ARRAY-MESSAGE | NO-ARRAY-MESSAGE**

Specifies whether the DataServer sends multiple result rows in a single logical network message.

The default is ARRAY-MESSAGE.

**BIND-WHERE | NO-BIND-WHERE**

This option is available only for the DataServer for ORACLE.

Specifies whether the DataServer uses ORACLE bind variables or literals in WHERE clauses. If you use NO-BIND-WHERE, the DataServer uses literals. Bind variables can improve performance, but ORACLE produces some unexpected results for some data types.

The default is BIND-WHERE.

**CACHE-SIZE integer [ROW | BYTE]**

Specifies the maximum cache size the DataServer can use when fetching records for a lookahead or standard cursor. You can optionally specify the size of the cache information in either bytes or records. The following values are for ORACLE.

The default is 1024 for standard cursors and 8192 for lookahead cursors.

If you use the byte option, the byte maximum is 65535 bytes and the byte minimum specifies the number of bytes contained in a single record. For joins, you must specify the number of bytes contained in two records.

If you use the row option, the row maximum equals the maximum number of records that can be fit in 65535 bytes. The row minimum is 1 row for a single table and 1 rows for a join.
The default is 30000.

\{
  \{ DEBUG \ { SQL | EXTENDED diag-option } \ } | NO-DEBUG
\}

Specifies whether the DataServer should print debugging information for the query to the dataserv.1g file.

The SQL option prints the SQL executed by the DataServer against the non-OpenEdge DBMS. The extended option prints additional information, such as cursor statistics. The information you get when you use the EXTENDED option can be helpful in setting your parameters.

The default is NO-DEBUG.

EXTENDED diag-option

The syntax for the diagnostic options is as follows:

**Syntax**

<table>
<thead>
<tr>
<th>EXTENDED CURSOR</th>
<th>DATA-BIND</th>
<th>PERFORMANCE</th>
<th>VERBOSE</th>
</tr>
</thead>
</table>

For more information, see the OpenEdge DataServer Guides (*OpenEdge Data Management: DataServer for Microsoft SQL Server*, *OpenEdge Data Management: DataServer for ODBC*, and *OpenEdge Data Management: DataServer for Oracle*).

**HINT**

This option is only available for the DataServer for ORACLE.

Specifies the ORACLE hint syntax that the DataServer passes directly to the ORACLE DBMS as part of the query. This allows you to control which hints are passed as opposed to the index hints that the DataServer passes when appropriate.

**INDEX-HINT | NO-INDEX-HINT**

This option is available only for the DataServer for ORACLE.

Specifies whether the DataServer provides index hints to the ORACLE DBMS. INDEX-HINT places index hints in the generated SQL; NOINDEX-HINT prevents the use of index hints.

The default is INDEX-HINT.

**JOIN-BY-SQLDB | NO-JOIN-BY-SQLDB**

Specifies whether the non-OpenEdge DBMS can perform joins when possible, which usually improves performance.

The default is JOIN-BY-SQLDB.

**LOOKAHEAD | NO-LOOKAHEAD**

Specifies whether the DataServer uses lookahead or standard cursors. Lookahead cursors fetch as many records as can fit into the allocated cache, which reduces the number of database accesses and improves performance.
The default is LOOKAHEAD, except with statements that use an EXCLUSIVE lock.

**ORDERED-JOIN**

Specifies that the DataServer embed the ORDERED hint syntax in the SQL it generates. Applies to ORACLE only.

**REVERSE-FROM**

Specifies that tables are joined in the reverse order in which they appear in the FROM clause. Applies to ORACLE only.

**SEPARATE-CONNECTION | NO-SEPARATE-CONNECTION**

Creates a new connection for each cursor that the DataServer opens. Applies to the OpenEdge DataServer for ODBC only.

**Example**

The following code fragment illustrates a QUERY-TUNING phrase in a FOR EACH statement. In this example, the DataServer uses lookahead cursors with a cache size of 32K and records debugging information:

```sql
FOR EACH Customer, EACH Order OF Customer WHERE Order.OrdNum > 20
  BY Customer.CustNum
  QUERY-TUNING(LOOKAHEAD CACHE-SIZE 32768 DEBUG EXTENDED)
  TRANSACTION:
```

**Note**

For the DataServer for ORACLE, all options of the QUERY-TUNING phrase are effective at both compile and run time, except INDEX-HINT, NO-INDEX-HINT, JOIN-BY-SQLDB, and NO-JOIN-BY-SQLDB, which are only effective at compile time.

For more information on the QUERY-TUNING phrase, see the OpenEdge DataServer Guides (OpenEdge Data Management: DataServer for Microsoft SQL Server, OpenEdge Data Management: DataServer for ODBC, and OpenEdge Data Management: DataServer for Oracle).

**See also**

DO statement, FOR statement, OPEN QUERY statement, REPEAT statement

---

**QUIT statement**

 Raises the QUIT condition. By default, this exits from the ABL session and returns to the operating system. When QUIT is executed from within a procedure running on an AppServer, it terminates the ABL session running on the AppServer, causing the AppServer server to shut down and returns to the ABL client session from which it was spawned.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

QUIT

**Example**

This procedure displays a menu. If you choose the last menu item, Exit ABL, the procedure processes the QUIT statement.
QUOTER function

Converts the specified data type to CHARACTER and encloses the results in quotes when necessary.

The QUOTER function is intended for use in QUERY-PREPARE where a character predicate must be created from a concatenated list of string variables to form a WHERE clause. In order to process variables, screen values, and input values so that they are suitable for a query WHERE clause, it is often necessary to enclose them in quotes. For example, European-format decimals and character variables must always be enclosed in quotes. You can use the Quoter function to meet that requirement.

Syntax

```
QUOTER (expression [, quote-char [, null-string ]])
```

**expression**

An expression in the data type that you want to convert to character and enclose with quotes.

Notes

- To modify the QUIT statement, add the ON QUIT phrase to a block.
- If QUIT is executed during a transaction, the AVM commits the transaction before exiting.

See also

ON QUIT phrase, STOP statement

r-quit1.p

```abl
DEFINE SUB-MENU cusmaint1
  MENU-ITEM crecust LABEL "Create New Customer"
  MENU-ITEM chgcust LABEL "Change Existing Customer"
  MENU-ITEM delcust LABEL "Delete Customer"
  MENU-ITEM prtcust LABEL "Print Customer List"
  MENU-ITEM extcust LABEL "Exit ABL".

DEFINE MENU mainbar MENUBAR
  SUB-MENU cusmaint1 LABEL "Customer".

ON CHOOSE OF MENU-ITEM crecust
  RUN newcust.p.

ON CHOOSE OF MENU-ITEM chgcust
  RUN chgcust.p.

ON CHOOSE OF MENU-ITEM delcust
  RUN delcust.p.

ON CHOOSE OF MENU-ITEM prtcust
  RUN prncust.p.

ON CHOOSE OF MENU-ITEM extcust
  QUIT.

ASSIGN
  CURRENT-WINDOW:MENUBAR = MENU mainbar:HANDLE
  CURRENT-WINDOW:VISIBLE = TRUE.

WAIT-FOR WINDOW-CLOSE OF CURRENT-WINDOW.
```
**quote-char**

Either a single or double quote, enclosed in the opposite: "" or ". The default is double quote. Passing ? for this argument results in double quotes.

**null-string**

The string you want for an unknown value: the word NULL or "" for example. The default is an unquoted question mark, which is the Unknown value (?).

For example, the following code:

```sql
DEFINE VARIABLE mychar As CHARACTER NO-UNDO INITIAL "Lift Line Skiing".
... qhandle:QUERY-PREPARE("FOR EACH Customer WHERE Customer.Name = " + QUOTER(mychar))
```

Would produce this prepare-string:

```sql
FOR EACH Customer WHERE Customer.Name = "Lift Line Skiing".
```

**Notes**

- To address the situation where an Unknown value (?) in a list of concatenated strings could cause the entire string to be unknown and the QUERY-PREPARE to fail, the QUOTER function does not return the Unknown value (?) if the <expression> argument is unknown. Instead, it returns a known character value consisting of an UNQUOTED question-mark, by default, or the 3rd argument, if it is present.

- Also, in this situation, a quoted question-mark is not used because it is interpreted as string data in a WHERE clause. After the concatenation is complete, the AVM supplies a normal question mark.

For example, the following code:

```sql
DEFINE VARIABLE mychar As CHARACTER NO-UNDO.
... mychar = ?.
qhandle:QUERY-PREPARE("FOR EACH Customer WHERE Customer.Name = " + QUOTER(mychar)).
```

Would produce this prepare-string:

```sql
FOR EACH Customer WHERE Customer.Name = ?.
```

However, giving the 3rd parameter as "NULL" produces NULL rather than ?.

- For noncharacter data types, if <expression> is of type DECIMAL, INT64, INTEGER, DATE, DATETIME, DATETIME-TZ, and so on, the following occurs:
  - The <expression> is converted to character and enclosed in quotes. The conversion is similar to the EXPORT format. DATE types, however, always have the 4-digit year.
R-INDEX function

- Data types with no DISPLAY format like MEMPTR and LVARBINARY return the Unknown value (?).
- If a data type is of type RAW, it is converted to base 64.

For example, the following code:

```
DEFINE VARIABLE mydec As DECIMAL NO-UNDO INITIAL 12.34.
... qhandle:QUERY-PREPARE("FOR EACH Customer WHERE Customer.Balance = " + QUOTER(mydec)).
```

Would produce this prepare-string:

```
FOR EACH Customer WHERE Customer.Balance = "12.34".
```

This is especially important for European format decimals that look like 12,34 and would not compile in the above statement unless they are enclosed in quotes.

- If `<expression>` is of data type CHARACTER, internal quotes are doubled. If the first and last byte are already quotes, then it is assumed that the quoting has already been done, and no further quotes are applied.
- You can use the QUOTER function with an object reference for a class instance to obtain a unique object identifier within the session as a quoted character string.

R-INDEX function

Returns an INTEGER value that indicates the position of the target string within the source string. In contrast to the INDEX function, R-INDEX performs the search from right to left.

Syntax

```
R-INDEX(source, target [, starting ])
```

source

A constant, field name, variable name, or expression that results in a CHARACTER or LONGCHAR value.

target

A CHARACTER or LONGCHAR expression whose position you want to locate in source. If target does not exist within source, R-INDEX returns 0.

If a starting parameter is not specified, then the search for the target pattern begins at the right-most character. Even though the search is started from the right, the target position is calculated from the left. For example, this code returns a 3 rather than a 2:

```
R-INDEX("abcd" , "c")
```
**starting**

An integer that specifies the begin point for the search. The search is right-to-left and starts from the starting point. For example, this statement returns 1

```
R-INDEX("abcdefabcdef","abc",6).
```

**Examples**

This procedure prompts you to enter a character string and a pattern to match against the string. It then displays the starting position of the string where the pattern was found.

```
DEFINE VARIABLE rindx AS INTEGER NO-UNDO.
DEFINE VARIABLE source AS CHARACTER NO-UNDO FORMAT "X(45)".
DEFINE VARIABLE target AS CHARACTER NO-UNDO FORMAT "X(45)".

REPEAT:
  PROMPT-FOR source LABEL "Enter a character string to do pattern matching:" WITH FRAME s1 CENTERED.
  PROMPT-FOR target LABEL "Enter a pattern to match in the string:" WITH FRAME t1 CENTERED.
  rindx = R-INDEX(INPUT source, INPUT target).
  IF rindx < > 0 THEN DO:
    DISPLAY "The target pattern:" INPUT target NO-LABEL
    "last appears in position" rindx NO-LABEL SKIP WITH FRAME r1 ROW 12 CENTERED.
    DISPLAY "in the source string:" INPUT source NO-LABEL WITH FRAME r1 ROW 12 CENTERED.
    HIDE FRAME r1.
  END.
  IF rindx = 0 THEN DO:
    DISPLAY "The target pattern:" INPUT target NO-LABEL
    "could not be found" SKIP
    WITH FRAME r2 ROW 12 CENTERED.
    DISPLAY "in the source string:" INPUT source NO-LABEL
    WITH FRAME r2 ROW 12 CENTERED.
    HIDE FRAME r2.
  END.
END.
```

This example also uses a starting value:
r-rndex.p

DEFINE VARIABLE mark AS INTEGER NO-UNDO.
DEFINE VARIABLE line-width AS INTEGER NO-UNDO.
DEFINE VARIABLE paragraph AS CHARACTER NO-UNDO.

paragraph = "The course centers around an existing small " + "application that you modify to improve performance. Our highly-qualified instructors demonstrate proven analysis and coding techniques and provide tips for making the most of your ABL code. You are encouraged to bring your own application problems to class and actively participate in class discussions and hands-on lab exercises."

SET line-width LABEL "Justify with how many characters wide?"
VALIDATE(line-width >= 20 AND line-width <= 70, "Must be between 20 and 70 for this example.")
WITH SIDE-LABELS FRAME ask.

FORM paragraph FORMAT "x(72)"
WITH DOWN NO-LABELS USE-TEXT.

DISPLAY "L" + FILL("-", line-width - 2) + "R" @ paragraph.
DOWN.

DO WHILE LENGTH(paragraph) > line-width:
    mark = R-INDEX(paragraph, " ", line-width).
    DISPLAY SUBSTRING(paragraph, 1, mark) @ paragraph.
    DOWN.
    paragraph = SUBSTRING(paragraph, mark + 1).
END.

IF paragraph <> "" THEN
    DISPLAY paragraph.

Notes

• If either operand is case sensitive, then the R-INDEX function is also case sensitive.

• If either the source string or target pattern is null, the result is 0.

• The R-INDEX function is double-byte enabled. You can specify target and source strings for the R-INDEX function that contain double-byte characters.

See also INDEX function, LOOKUP function

RADIO-SET phrase

Describes a radio set representation for a field or variable. The RADIO-SET phrase is an option of the VIEW-AS phrase.

Note: Does not apply to SpeedScript programming.
Syntax

RADIO-SET

[ HORIZONTAL [ EXPAND ] | VERTICAL ]
[size-phrase ]
RADIO-BUTTONS label, value [, label, value ] ...
[ TOOLTIP tooltip ]

HORIZONTAL

Specifies that the radio buttons are aligned horizontally. Vertical alignment is the default.

VERTICAL

Specifies that the radio buttons are aligned vertically. Because this is the default alignment, you do not have to supply this attribute.

EXPAND

Pads all button labels to be the width of the widest radio button label. This ensures that the buttons are evenly spaced. Use this option only in conjunction with the HORIZONTAL option. If you do not specify this option, the individual radio buttons are spaced evenly if the lengths of the labels vary.

size-phrase

Specifies the outside dimensions of the radio-set widget. This is the syntax for size-phrase:

Syntax

{ SIZE | SIZE-CHARS | SIZE-PIXELS } width BY height

For further information, see the SIZE phrase reference entry.

RADIO-BUTTONS label, value [, label, value ] ...

A list of radio buttons whose selections are mutually exclusive. Each button is composed of a label and value pair. The label is a character string that is the label for the radio button. The value is the value to be assigned to the field or variable if the radio button is selected; value must be a valid value for the field or variable.

You can designate a character within each label as a navigation mnemonic in Windows. Indicate the character by preceding it with an ampersand (&). When the radio set is displayed, the mnemonic is underlined. The user can choose to the specific button by pressing ALT and the underlined letter.

Note: If two or more buttons of a radio set use the same label, the AVM uses only the value of the first button.
TOOLTIP tooltip

Allows you to define a help text message for a text field or text variable. The AVM automatically displays this text when the user pauses the mouse button over a text field or text variable for which a tooltip is defined.

You can add or change the TOOLTIP option at any time. If TOOLTIP is set to "" or the Unknown value (?), then the tooltip is removed. No tooltip is the default. The TOOLTIP option is supported in Windows only.

**Example**

This procedure displays a radio set that consists of three radio buttons and prompts the user to select one of the buttons. When the user selects the button, the program displays the text “This event occurred on” and the date value of selected button.

**r-radio1.p**

```plaintext
DEFINE VARIABLE hist-date AS DATE NO-UNDO
   FORMAT "99/99/9999" INITIAL 07/04/1776
VIEW-AS RADIO-SET RADIO-BUTTONS
   "Declaration of Independence", 07/04/1776,
   "Lee Surrenders to Grant", 04/07/1865,

FORM hist-date
   WITH FRAME main-frame NO-LABELS TITLE "Dates in US History".

ON VALUE-CHANGED OF hist-date DO:
   ASSIGN hist-date.
   DISPLAY "This event occurred on " + STRING(hist-date) FORMAT "x(60)"
      WITH FRAME main-frame.
END.

ENABLE hist-date WITH FRAME main-frame.APLY "VALUE-CHANGED" TO hist-date.
WAIT-FOR WINDOW-CLOSE OF CURRENT-WINDOW.
```

**See also**

VIEW-AS phrase

---

**RANDOM function**

Returns a random INTEGER value between two integers (inclusive).

---

**Note:** This function returns a number from a pseudorandom sequence of numbers rather than a truly random sequence.

The Alternate Random Number Generator (-rand) parameter determines whether the same sequence of random numbers is generated for each session. For information on this parameter, see OpenEdge Deployment: Startup Command and Parameter Reference.

**Syntax**

```
RANDOM ( low, high )
```
An integer expression that is the lower of the two expressions you are supplying to the RANDOM function.

An integer expression that is the higher of the two expressions you are supplying to the RANDOM function.

Often when you set up a database for testing purposes, you want to generate many records without actually keying in data for each record. The r-random.p procedure generates 10 Order records and a random number of OrderLines for each Order record.

```
DEFINE VARIABLE onum  AS INTEGER NO-UNDO.
DEFINE VARIABLE olnum AS INTEGER NO-UNDO.
DO onum = 1 TO 10 TRANSACTION:
   CREATE Order.
   ASSIGN
      Order.OrderNum = onum
      Order.OrderDate = TODAY.
   DO olnum = 1 TO RANDOM(1,9):
      CREATE OrderLine.
      ASSIGN
         OrderLine.LineNum = olnum
         OrderLine.ItemNum = olnum.
   END.
END.
```

Extracts bytes from a field.

```
RAW ( field [, position [, length ] ] )
```

Any field from which you want to extract bytes.

An integer expression that indicates the position of the first byte you want to extract from field. The default value of position is 1.

An integer expression that indicates the number of bytes you want to extract from field. If you do not use the length argument, RAW uses field from position to end.
Example

This procedure extracts bytes from the Name field of the first Customer, starting at byte 8, and writes 4 bytes to the variable r1:

```
r-rawfct.p
/*You must connect to a non-OpenEdge demo database to run this procedure*/
DEFINE VARIABLE r1 AS RAW NO-UNDO.
FIND FIRST Customer NO-LOCK.
r1 = RAW(Customer.Name,8,4).
```

Notes

- If position is less a 1, or length is less than 0, the AVM returns a run-time error.
- If (position + length - 1) is greater than the length of the field from which you are extracting the bytes, the AVM returns a run-time error.

See also

GET-BYTE function, LENGTH statement, PUT-BYTE statement, RAW statement

RAW statement (ORACLE only)

Writes bytes to a field.

Syntax

```
RAW ( field [ , position [ , length ] ] ) = expression
```

field

The field in which you want to store expression.

position

An integer expression that indicates the position in field where you want to store expression. The default for position is 1.

length

An integer expression that indicates the number of positions you want to replace in field. If you do not use the length argument, RAW puts expression into field from position to end. ABL treats variable-length fields and fixed-length fields differently. See the Notes section for more information.

expression

A function or variable name that returns data and results in the bytes that you want to store in field.

Notes

- In a variable length field, if (position + length - 1) is greater than the length of field, the AVM pads the field with nulls before it performs the replacement.
- In a fixed length field, if (position + length - 1) is greater than the length of field, the AVM returns a run-time error. If (position + length - 1) is less then the length of field, the AVM pads the field with nulls so that it remains the same size.
RAW-TRANSFER statement

Copies a record wholesale from a source to a target.

Syntax

```
RAW-TRANSFER
{  [ BUFFER ] buffer TO [ FIELD ] raw-field
  |  [ FIELD ] raw-field TO [ BUFFER ] buffer
  |  [ BUFFER ] buffer TO [ BUFFER ] buffer
}
[ NO-ERROR ]
```

BUFFER

Specifies a parameter is a buffer.

`buffer`

A source or target database record.

**Note:** If the source buffer contains only a partial field list, RAW-TRANSFER fails.

FIELD

Specifies a parameter is a raw-field.

`raw-field`

A source or target data field of type RAW.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.
• Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

• Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

• NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

• A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

• When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

• If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

Example

The following ABL example performs a RAW-TRANSFER of a newly created Customer record to the Record field of Replication-Log table:

```
TRIGGER PROCEDURE FOR REPLICATION-CREATE OF Customer.
CREATE Replication-Log.
ASSIGN
  Replication-Log.Taskid = DBTASKID(LDBNAME(BUFFER Replication-Log))
  Replication-Log.Table = 'Customer'
  Replication-Log.Action = 'CREATE'.
RAW-TRANSFER Customer TO Replication-Log.Record.
```

For more information on database replication, see *OpenEdge Data Management: Database Administration*. 
Notes

- The RAW-TRANSFER statement has several variations:
  - The “buffer to raw-field” variation copies the entire record from the buffer to the raw field, prepending information on the source schema to the raw field.
  - The “raw-field to buffer” variation first checks that the source schema information prepended to the raw field matches the schema of the buffer. Then it creates a target record, if necessary. Finally it updates each key field in the new record using values from the raw field, which forces indexing to occur.
  - The “buffer to buffer” variation is the same as the “raw-field to buffer” variation, except that the source is a record in another buffer.

- The RAW-TRANSFER statement respects database triggers.

- You can marshal an OpenEdge database record so that it can be sent across sockets by using the RAW-TRANSFER statement to put the record into a RAW variable and then copying the RAW variable to a MEMPTR that is being written to a socket. Use the PUT-BYTES function to do this. You can unmarshal database records by using the GET-BYTES function and then RAW-TRANSFER.

- At run time, the RAW-TRANSFER statement:
  - Checks that the signatures of the source data and the target data match.
  - Compares source and target code page ids, and (if they are present and different) translates the source’s character data, writing any warnings to the database log file and raising any error conditions.
  - Creates the target record, if none exists, and runs all appropriate CREATE triggers (unless the DISABLE TRIGGERS FOR LOAD option is active for the target).
  - Registers changes in key fields with the index manager by updating each key field in the target when it differs from the source.
  - Copies all data from the source record to the target record.
  - Executes ASSIGN triggers for any modified fields (unless the DISABLE TRIGGERS FOR LOAD option is active for the target).

- When using the RAW-TRANSFER statement to copy a record that contains a BLOB or CLOB field, the AVM skips the BLOB or CLOB field and stores the Unknown value (?) in the BLOB or CLOB field of the target record.

See also

DISABLE TRIGGERS statement, LDBNAME function, RAW-TRANSFER( ) method, RECORD-LENGTH function

READKEY statement

Reads one keystroke from an input source and sets the value of LASTKEY to the keycode of that keystroke. Use the READKEY statement when you want to look at each keystroke a user makes and take some action based on that keystroke.
READKEY statement

**Note:** Does not apply to SpeedScript programming.

**Caution:** If you are executing the READKEY statement while blocking on a .NET main form, a user action can unconditionally shut down the ABL application. For more information, see the WAIT-FOR statement (.NET and ABL) reference entry.

**Syntax**

```
READKEY [ STREAM stream | STREAM-HANDLE handle ] [ PAUSE n ]
```

**STREAM stream**

Specifies the name of a stream. If you do not name a stream, the AVM uses the unnamed stream. See the DEFINE STREAM statement.

**STREAM-HANDLE handle**

Specifies the handle to a stream. If handle it is not a valid handle to a stream, the AVM generates a run-time error. Note that stream handles are not valid for the unnamed streams. See the chapter on alternate I/O sources in OpenEdge Development: Programming Interfaces for more information on streams and stream handles.

**PAUSE n**

The READKEY statement waits up to n seconds for a keystroke. If you do not press a key during that amount of time, READKEY ends, and sets the value in LASTKEY to -1.

PAUSE 0 causes READKEY to immediately return a value. If no character is available, READKEY sets the value of LASTKEY to -1. Use this form of READKEY to do polling through UNIX pipes or terminal ports.

**Example**

In the following procedure, when the user presses a key, the READKEY statement reads the keystroke and stores the character code value of that key (the key code) as the value of LASTKEY. The CHR function converts the character code value into a character value. If the character value is a Y, the AVM deletes the Customer. KEYFUNCTION determines the function of the LASTKEY. If that function is END-ERROR, the AVM exits the block, ending the procedure.

```
r-readky.p
```

```
FOR EACH Customer:
    Customer.State WITH 1 DOWN.
    MESSAGE "If you want to delete this customer, press Y".
    MESSAGE "Otherwise, press any other key.".
    READKEY.
    IF CHR(LASTKEY) = "Y" THEN DELETE Customer.
    ELSE IF KEYFUNCTION(LASTKEY) = "END-ERROR" THEN LEAVE.
END.
```

**Notes**

- If you use READKEY, it intercepts any input from the user. Thus no widgets receive the input. To pass the input to a widget, you must use the APPLY statement.

- The READKEY function is double-byte enabled. The READKEY function returns values only after the input method places the data in the keyboard buffer. It returns the key code
of the most recent key sequence returned from the keyboard buffer. A key sequence is the set of keystrokes necessary to generate one character or function key event in ABL.

- If the current input source is a file, then READKEY reads the next character from that file and returns the value of that character (1 to 255) to LASTKEY. READKEY does not translate periods (.) in the file into the ENDKEY value. It does translate end of line into RETURN (13), but it cannot read any special keys, such as function keys.

  When the AVM reaches the end of the file, it sets the value of LASTKEY to -2, but does not close the input file. At that point, an APPLY LASTKEY (same as APPLY -2) raises the ENDKEY condition.

- If the current input source is a UNIX pipe, any timer you set with the PAUSE option might expire before READKEY can read a character. If so, LASTKEY is set to -1.

- If the last key typed is an invalid character sequence, READKEY sets the value of LASTKEY to -1.

- READKEY counts to determine whether an UNDO, RETRY should be treated as UNDO, NEXT, and whether UNDO, NEXT should be treated as UNDO, LEAVE. This presents infinite loops.

- For more information on monitoring keystrokes, see *OpenEdge Development: Programming Interfaces*.

**See also**  
DEFINE STREAM statement, LASTKEY function, Stream object handle

---

**RECID function**

Returns the unique internal identifier of the database record currently associated with the record buffer you name. This internal identifier has the data type RECID, a four-byte value that is supported by OpenEdge databases and some non-OpenEdge DataServers.

This function is supported for backward compatibility. For most applications, use the ROWID function, instead. For more information, see the **ROWID function** reference entry.

**Syntax**

```plaintext
RECID ( record )
```

*record*

The name of the record whose RECID you want.

To use the RECID function with a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the **Record phrase** reference entry for more information.
**Example**

You might decide that you do not want to lock a record until the user starts to update that record. In the example procedure, the FIND statement reads a Customer record without locking the record. The RECID function puts the internal database identifier of that record in the `crecid` variable. If the user decides to update the `CreditLimit` field, the procedure finds the record again using the value in `crecid`. The second FIND statement reads the record again, this time placing an EXCLUSIVE-LOCK on it. Because the record is first found with NO-LOCK, it is possible for the record to be updated by another user after the first FIND and before the second.

```
DEFINE VARIABLE response AS LOGICAL NO-UNDO.
DEFINE VARIABLE crecid AS RECID NO-UNDO.

REPEAT:
    PROMPT-FOR Customer.CustNum.
    FIND Customer NO-LOCK USING Customer.CustNum.
    crecid = RECID(Customer).
    DISPLAY Customer.name.
    response = YES.
    UPDATE response LABEL "Update credit-limit ?".
    IF response THEN DO:
        FIND Customer WHERE RECID(Customer) = crecid EXCLUSIVE-LOCK.
        UPDATE Customer.CreditLimit.
    END.
END.
```

**Notes**

- Use the RECID function to rapidly retrieve a previously identified record, even if that record has no unique index.

- If you want a called procedure to use the same record as a calling procedure, use the RECID function to ensure that you are retrieving the same record. Use a SHARED variable to communicate the RECID of a record from one procedure to another. The second procedure can then find the same record. This is an alternative to using shared buffers.

- Avoid storing RECID values in database fields because those RECDs will change if you dump and reload the database.

- You do not have to explicitly check to see whether a record is AVAILABLE before using the RECID function. The RECID function returns the Unknown value (?) if a record cannot be accessed.

This example displays a RECID only when a record can be accessed:

```
DISPLAY (IF AVAILABLE Customer THEN RECID(Customer) ELSE ?).
```

Directly reference RECID even if a record cannot be found:

```
FOR EACH Customer NO-LOCK:
    DISPLAY Customer.CustNum.
END.
DISPLAY RECID(Customer).
```

**See also**

DEFINE BUFFER statement, DEFINE VARIABLE statement, Record phrase, ROWID function
Record phrase

Identifies the record or records you want to verify using the CAN-FIND function, retrieve with a FIND statement, query with a FOR statement or OPEN QUERY statement, or preselect in a DO or REPEAT block.

The Record phrase syntax describes three kinds of information:

- Qualifies the record(s) to access in the table
- Specifies the index to use when locating records
- Defines the type of record lock to apply when the records are read

Syntax

```
{ record [ field-list ] }
[ constant ]
[ [ LEFT ] OUTER-JOIN ]
[ OF table ]
[ WHERE expression ]
[ USE-INDEX index ]
[ USING [ FRAME frame ] field
  [ AND [ FRAME frame ] field ] ... ]
[ SHARE-LOCK | EXCLUSIVE-LOCK | NO-LOCK ]
[ NO-PREFETCH ]
```

Note: You can specify the OUTER-JOIN, OF, WHERE, USE-INDEX, and USING options in any order. You cannot use field-list in an OPEN QUERY statement. You cannot use OUTER-JOIN or EXCLUSIVE-LOCK in a CAN-FIND function.

record

The name of a database table, a temp-table that you named in a DEFINE TEMP-TABLE statement, or a buffer that you named in a DEFINE BUFFER statement. If record is the name of a table, record actually refers to the default buffer of the specified database table or temp-table. Also, the default buffer for a database table is always scoped to the main external procedure or class definition block even if you reference the default buffer in a sub-block, such as an internal procedure or method of a class.

To access a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. Use this syntax to refer to a record in a table for a specific database:

Syntax

```
dbname.tablename
```

You do not have to qualify the reference if record is the name of a defined buffer.
field-list

Specifies a list of fields to include or exclude when you retrieve records using a FOR, DO PRESELECT, or REPEAT PRESELECT statement. Field lists are also available for queries using the DEFINE QUERY statement, except when the query is against a temp-table. Following is the syntax for field-list:

Syntax

```
{ FIELDS [ ( [ field ... ] ) ]
   | EXCEPT [ ( [ field ... ] ) ]
}
```

The FIELDS option specifies the fields you want to include in a record retrieval, and the EXCEPT option specifies the fields that you want to exclude from a record retrieval. The field parameter is the name of a single field in the specified table. If field is an array reference, the whole array is retrieved even if only one element is specified. Specifying FIELDS with no field references causes the AVM to retrieve sufficient information to extract the ROWID value for a specified record (returnable using the ROWID function). Specifying EXCEPT with no field references or specifying record without a field-list causes the AVM to retrieve a complete record.

This statement retrieves only the Name and Balance fields of the Customer table:

```
FOR EACH customer FIELDS (name balance): DISPLAY name balance.
```

This statement retrieves all fields of the Customer table except the Name and Balance fields:

```
FOR EACH Customer EXCEPT (Name Balance):
```

When you specify a field list, the AVM might retrieve additional fields or the complete record depending on the type of retrieval operation and the DataServer that provides the record. Thus, the AVM:

- Retrieves any additional fields required by the client to complete the record selection.
- Retrieves a complete record when the record is fetched with EXCLUSIVE-LOCK. This ensures proper operation of updates and the local before-image (BI) file. For information on the local BI file, see OpenEdge Data Management: Database Administration.
- Retrieves a complete record for DataServers that do not support SHARE-LOCK. For more information, see the appropriate DataServer guides (OpenEdge Data Management: DataServer for Microsoft SQL Server, OpenEdge Data Management: DataServer for ODBC, and OpenEdge Data Management: DataServer for Oracle).

Note: Always specify fields that you plan to reference in the field list. Only those extra fields that the client requires for record selection are added to the specified field list. The AVM distributes record selection between the client and server depending
on a number of factors that change with each OpenEdge release. Therefore, never rely on fields that you did not specify but which the AVM fetches for its own needs; they might not always be available. There is no additional cost to specify a field in the list that you otherwise expect the AVM to provide.

This statement retrieves the Customer.CustNum field in addition to those specified in the field lists because it is required to satisfy the inner join between the Customer and Order tables:

```
FOR EACH Customer FIELDS(Name) NO-LOCK,
    EACH Order FIELDS(OrderNum SalesRep) OF Customer NO-LOCK:
```

However, do not rely on the AVM to always provide such extra fields. For reliability, add the CustNum field to the Customer field list as follows:

```
FOR EACH Customer FIELDS(Name CustNum) NO-LOCK,
    EACH Order FIELDS(OrderNum SalesRep) OF Customer NO-LOCK:
```

**constant**

The value of a single component, unique, primary index for the record you want. This option is not supported for the OPEN QUERY statement:

```
FIND Customer 1.
```

The AVM converts this FIND statement with the *constant* option of 1 to the following statement:

```
FIND Customer NO-LOCK WHERE Customer.CustNum = 1.
```

The CustNum field is the only component of the primary index of the Customer table.

If you use the *constant* option, you can use it only once in a single Record phrase, and it must precede any other options in the Record phrase.

**LEFT OUTER-JOIN**

Specifies a left outer join between *record* and the table (or join) specified by the previous Record phrase(s) of an OPEN QUERY statement. A left outer join combines and returns data from the specified tables in two ways. First, the records selected for the table (or join) on the left side combine with each record selected using the OF or WHERE options from the table on the right (*record*). Second, the records selected for the table (or join) on the left side combine with the Unknown value (?) for the fields from the table on the right (*record*) for which no records are selected using the OF or WHERE options. The join is ordered according to the given sort criteria starting with the left-most table in the query.
Record phrase

**Note:** If you specify the OUTER-JOIN option, you must also specify the OUTER-JOIN option in all succeeding Record phrases of the query to obtain a left outer join. That is, for multiple Record phrases, all joins in the query following your first left outer join must also be left outer joins. Otherwise, the result is an inner join for all records up to the last inner join in the query. For more information, see *OpenEdge Getting Started: ABL Essentials*.

The OUTER-JOIN option is supported only in the OPEN QUERY statement and in Record phrases specified after the first Record phrase in the OPEN QUERY statement. The LEFT keyword is optional with OUTER-JOIN. If you specify OUTER-JOIN, you must also specify the OF option, WHERE option, or any combination of the OF and WHERE options. These options are required to select record (the right-most table) for the specified left outer join. For example:

```plaintext
OPEN QUERY q1 PRESELECT EACH Customer,
  FIRST Order OUTER-JOIN OF Customer WHERE Order.OrderNum < 50
```

This query specifies a left outer join between Customer and Order, and also between that join and OrderLine. Thus, for each Customer record that has no Orders or has no Orders with an OrderNum less than 50, the query returns the Customer fields and ? for all fields of the Order and OrderLine tables. In addition, if there are no OrderLine records with ItemNum less than 15 for any selected Customer and Order, the query returns ? for all fields of OrderLine. Otherwise, it returns each Customer record along with its first selected Order record and OrderLine record.

In all statements where multiple Record phrases are allowed (including DO, FOR, OPEN QUERY, and REPEAT statements), the default join (without the OUTER-JOIN option) is an inner join between record and the table (or join) specified by the previous Record phrase(s). An inner join returns the records selected for the table (or join) on the left side combined with each selected record from the table on the right (record). For an inner join, no records are returned for the table (or join) on the left for which no record is selected from the table on the right (record).

The following query specifies an inner join between Customer and Order, and also between that join and OrderLine. Thus, this query only returns Customer records that have at least one Order with OrderNum less than 50 that also have at least one OrderLine with ItemNum less than 15, and it returns just the first such Order and OrderLine for each Customer record.

```plaintext
OPEN QUERY q1 PRESELECT EACH Customer,
  FIRST Order OUTER-JOIN OF Customer WHERE Order.OrderNum < 50
```

**Note:** If you specify a Record phrase as an inner join, the current Record phrase and all preceding Record phrases in the query participate in contiguous inner joins, even if prior Record phrases specify the OUTER-JOIN option. Thus, for multiple Record phrases, all joins in the query up to the right-most inner join result in contiguous inner joins. For more information, see *OpenEdge Getting Started: ABL Essentials*. 

920
For more information on joins in ABL, see *OpenEdge Getting Started: ABL Essentials*.

**OF table**

Relates *record* to one other table specified by a table or buffer name (*table*). The relationship is based on common field names between *record* and *table* that also participate in a UNIQUE index for either *record* or *table*. When you use **OF** and the UNIQUE index is multi-field, all fields in the index participate in the match criteria. A reference to *table* must appear in a prior joined Record phrase in the same statement, or remain in scope from a prior record reading statement, such as a FIND statement.

**Note:** For the **OF** keyword to properly detect a relationship between two tables, only one such relationship is allowed.

In this example, the **OF** option relates the order table to the Customer table; thus the AVM selects the Customer record related to the Order record currently in use. The AVM converts the FIND statement with the **OF** option to a FIND statement with the **WHERE** option.

```
PROMPT-FOR Order.OrderNum.
FIND Order NO-LOCK USING Order.OrderNum.
DISPLAY Order.

FIND Customer OF Order NO-LOCK.
DISPLAY customer.
```

You can use **WHERE** to access related tables, whether or not the field names of the field or fields that relate the tables have the same name. For example:

```
FIND Customer NO-LOCK WHERE Customer.CustNum = Order.CustNum.
```

**WHERE expression**

Qualifies the records you want to access. The *expression* is a constant, field name, variable name, or expression whose value you want to use to select records. You can use the WHERE keyword even if you do not supply an *expression*. For example:

```
FOR EACH Customer NO-LOCK WHERE {*}
```

The WHERE clause may not work the same way against a DataServer as it does against the OpenEdge database. Refer to the appropriate DataServer Guide (*OpenEdge Data Management: DataServer for ODBC* or *OpenEdge Data Management: DataServer for Oracle*), for additional information on how this feature will perform.

**Note:** You cannot reference a BLOB or CLOB field in a WHERE clause.

In an OPEN QUERY statement or FOR statement, the WHERE clause can use the CONTAINS operator to reference a field with a word index. This is the syntax for the CONTAINS operator:
In this syntax, field represents a field in which a word index has been defined. The search-expression specifies one or more words to search for. It must evaluate to a string with this syntax:

**Syntax**

\[
\text{field \text{CONTAINS} \text{search-expression}}
\]

Each word is a word to search for. The ampersand (&) represents a logical AND; the vertical line (|), exclamation point (!), or caret (^) represent a logical OR. You can use an asterisk (*) as a wildcard, but only at the end of a word. Using an asterisk anywhere else in a word raises an error.

You can use parenthesis to establish precedence in the search string. For example, the following expression means to search for

Here is an example using the CONTAINS clause:

```
FOR EACH Item NO-LOCK WHERE Item.CatDescription CONTAINS "ski":
  DISPLAY Item.ItemName Item.CatDescription VIEW-AS EDITOR SIZE 60 BY 15.
END.
```

You can use parenthesis to establish presentness in the search string. For example, the following expression returns a subset of the catalog descriptions containing "ski":

```
WHERE Item.CatDescription CONTAINS "ski & (gog* ! pol*)"
```

**Note:** The CONTAINS option is not allowed in a FIND statement. If the session is started with the Version 6 Query (-v6q) parameter, the CONTAINS option is also not allowed in a FOR statement.

**Note:** For information about compiling, storing, and applying the UTF-8 word-break rules to a database, see OpenEdge Development: Internationalizing Applications.

**USE-INDEX index**

Identifies the index you want to use while selecting records. If you do not use this option, the AVM selects an index to use based on the criteria specified with the WHERE, USING, OF, or constant options.

**USING [FRAME frame] field [AND [FRAME frame] field] . . .**

One or more names of fields for selecting records. You must have previously entered each field you name in this option, usually with a PROMPT-FOR statement. The field must be viewed as a fill-in or text widget.
The USING option translates into an equivalent WHERE option:

\begin{verbatim}
PROMPT-FOR Customer.CustNum.
FIND Customer NO-LOCK USING Customer.CustNum.
\end{verbatim}

This FIND statement is the same as this statement:

\begin{verbatim}
\end{verbatim}

The CustNum field is a non-abbreviated index. However, if the Name field is an abbreviated index of the Customer table, the AVM converts the FIND statement with the USING option. For example:

\begin{verbatim}
PROMPT-FOR Customer.Name.
FIND Customer NO-LOCK USING Customer.Name.
\end{verbatim}

The following statement is a result of the previous one:

\begin{verbatim}
FIND Customer NO-LOCK WHERE Customer.Name BEGINS INPUT Customer.Name.
\end{verbatim}

SHARE-LOCK

Tells the AVM to put a SHARE-LOCK on records as they are read. Another user can read a record that is share locked, but cannot update it. By default, the AVM puts a SHARE-LOCK on a record when it is read (unless it uses a CAN-FIND function), and automatically puts an EXCLUSIVE-LOCK on a record when it is modified (unless the record is already EXCLUSIVE-LOCKed).

In a CAN-FIND function, NO-LOCK is the default. Also, CAN-FIND cannot use EXCLUSIVE-LOCK.

If you use the SHARE-LOCK option and the AVM tries to read a record that is EXCLUSIVE-LOCKed by another user, the AVM waits to read the record until the EXCLUSIVE-LOCK is released. The AVM displays a message to the user of that procedure, identifying the table that is in use, the user ID of the user, and the tty of the terminal using the table.

If you are using a record from a work table, the AVM disregards the SHARE-LOCK option.

EXCLUSIVE-LOCK

Tells the AVM to put an EXCLUSIVE-LOCK on records as they are read. Other users cannot read or update a record that is EXCLUSIVE-LOCKed, except by using the NO-LOCK option. They can access that record only when the EXCLUSIVE-LOCK is released. The AVM automatically puts a SHARE-LOCK on a record when it is read and automatically puts an EXCLUSIVE-LOCK on a record when it is updated.
If a record is read specifying EXCLUSIVE-LOCK, or if a lock is automatically changed to EXCLUSIVE-LOCK by an update, user’s read or update will wait if any other user SHARE-LOCKed or EXCLUSIVE-LOCKed the record.

When a procedure tries to use a record that is EXCLUSIVE-LOCKed by another user, the AVM displays a message identifying the table that is in use, the user ID of the user, and the tty of the terminal using the table.

If you are using a record from a work table, the AVM disregards the EXCLUSIVE-LOCK option. Also, CAN-FIND cannot use the EXCLUSIVE-LOCK option.

Specifying EXCLUSIVE-LOCK causes the AVM to retrieve complete records, even when the record is specified with field-list.

NO-LOCK

Tells the AVM to put no locks on records as they are read, and to read a record even if another user has it EXCLUSIVE-LOCKed.

Another user can read and update a record that is not locked. By default, the AVM puts a SHARE-LOCK on a record when it is read (unless it uses a CAN-FIND function, which defaults to NO-LOCK), and automatically puts an EXCLUSIVE-LOCK on a record when it is updated (unless the record is already EXCLUSIVE-LOCKed). A record that has been read NO-LOCK must be reread before it can be updated.

```
DEFINE VARIABLE rid AS ROWID NO-UNDO.
rid = ROWID(customer).
FIND Customer EXCLUSIVE-LOCK WHERE ROWID(Customer) = rid.
```

If a procedure finds a record and it places it in a buffer using NO-LOCK and you then refind that record using NO-LOCK, the AVM does not reread the record. Instead, it uses the copy of the record that is already stored in the buffer. To make sure the AVM gets a fresh copy of the record from the database, you must release all NO-LOCK buffers referencing the record or retrieve the record with EXCLUSIVE-LOCK. Note that you can use the Reread Nolock (-rereadnolock) startup parameter to change this default behavior.

When you read records with NO-LOCK, you have no guarantee of the overall consistency of those records because another user might be in the process of changing them. When values are assigned to indexed fields for a newly created record or are modified in an existing record, the index is immediately updated to reflect the change. However the copy of the data record in the buffers used by the database server might not be updated until later in the transaction. For example, the following procedure might display a CustNum of 0 if another user’s active transaction has created a record and assigned a value to the indexed field CustNum that is greater than 100:

```
FOR EACH Customer NO-LOCK WHERE Customer.CustNum >:
   DISPLAY Customer.CustNum.
END.
```

If you are using a record from a work table, the AVM disregards the NO-LOCK option.
NO-PREFETCH

Specifies that only one record is sent across the network at a time. If you specify field-list, only the specified fields and any additional fields required for record selection are sent. If you do not specify this option, the AVM can send more than one record from the server to the client in each network packet.

Examples

In the *r-recph.p* procedure, there are two Record phrases that make an inner join between the Customer and Order tables.

**r-recph.p**

```
FOR EACH Customer FIELDS(CustNum Name CreditLimit)
  WHERE Customer.CreditLimit GE 50000,
  EACH Order FIELDS(OrderNum OrderDate Terms) OF Customer:
  DISPLAY Customer.CustNum Customer.Name Customer.CreditLimit Order.Orderum
  Order.OrderDate Order.Terms.
END.
```

Using these Record phrases, the FOR EACH block reads a Customer record only if it has a CreditLimit value greater than 50000 and at least one Order record associated with it.

**r-recph2.p**

```
REPEAT:
  FIND NEXT Customer USE-INDEX country-post WHERE Customer.Name BEGINS "S"
    EXCLUSIVE-LOCK.
END.
```

In the *r-recph2.p* procedure, there is one Record phrase:

```
Customer USE-INDEX country-post WHERE Customer.Name BEGINS "S" EXCLUSIVE-LOCK
```

Using the zip index named country-post rather than the CustNum index (the primary index for the Customer table), the FIND statement reads only those Customer records that have a Name that begins with an s. The FIND also places an EXCLUSIVE-LOCK on each record as it is read. This lock is released at the end of the REPEAT block.

In the output of this procedure, all the Customer names begin with s and the customers are displayed in order by country and then postal code.

Notes

- Specifying a field list (field-list) for record can increase the performance of remote (network) record retrieval substantially over specifying record alone.

- If you reference an unfetched database field at run time, the AVM raises the ERROR condition. ABL does not perform a compile-time check to ensure that the field is fetched because the compiler cannot reliably determine how a particular record will be read (that is, whether it is retrieved using a FIND statement, retrieved with or without a field list, including additional fields to satisfy join conditions, etc.).

- Do not use a field list if you delete or update the record shortly after the record retrieval. Otherwise, the AVM reads the whole record, again, to complete the delete or update.
• You can specify the Field List Disable (-fldisable) startup parameter to cancel field list retrieval and force the AVM to retrieve complete records. This is a run-time client session parameter that is especially useful for deployed applications whose database triggers are later redefined to reference unfetched fields (raising the ERROR condition). Using -fldisable provides a workaround that allows the application to run (although more slowly) until the application can be fixed.

• You cannot specify field lists or joins in a FIND statement, or specify field lists in an OPEN QUERY statement.

• You cannot use the CONTAINS operator with a temp-table.

• If used, the CONTAINS operator must appear in the outer-most WHERE expression. You can combine it with other expressions at the outer level using the AND and OR operators. However, you cannot apply the NOT operator to a CONTAINS expression.

• You cannot reference a BLOB or CLOB field in a WHERE clause.

• Temp-tables and work tables can be used in join conditions specified with the OF option as long as the OF option requirements identified earlier in this section have been satisfied.

• Do not compare case-sensitive data with case-insensitive data in a WHERE expression. The AVM both cannot determine the results and does not raise the ERROR condition if you specify data with mixed case sensitivity in selection criteria because:
  – Mixed case sensitivity in selection criteria is handled differently by different DataServers.
  – Mixed case-sensitivity results for the same DataServer can be different depending on whether the query is resolved on the client or the server.
  – Some national languages do not support the concept of case sensitivity.

  Thus, such queries cannot be reliably resolved in any way.

• For SpeedScript, the only invalid option is USING FRAME.

• In a class definition, ABL treats the default buffer of a database table that you reference as an instance data member of the class. Therefore, you cannot access a default database buffer from a static member of a class, such as a static query or method; instead, you can define an alternate static buffer data member to access records of the database table from another static class member.

See also DEFINE QUERY statement, DO statement, FIND statement, FOR statement, OPEN QUERY statement, REPEAT statement

**RECORD-LENGTH function**

Returns the length of a record in a buffer as an INTEGER value.

**Syntax**

```
RECORD-LENGTH ( buffer )
```
REJECTED function

Returns the current REJECTED attribute setting for a ProDataSet temp-table buffer.

Syntax

```plaintext
REJECTED( buffer-name )
```

**buffer-name**

The name of a ProDataSet temp-table buffer.

**Notes**

- This function is typically used with the SAVE-ROW-CHANGES( ) method.
- The REJECTED function corresponds to the REJECTED attribute.
- You can invoke the REJECTED function from within a WHERE clause (unlike the corresponding attribute).

RELEASE statement

Verifies that a record complies with mandatory field and unique index definitions. It clears the record from the buffer and unites it to the database if it has been changed.

Syntax

```plaintext
RELEASE record [ NO-ERROR ]
```

**record**

The name of a record buffer.

To use RELEASE with a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that
RELEASE statement

contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

For the RELEASE statement, as an exception to the general rule, if a unique index constraint is violated the NO-ERROR clause is ignored when validating the record. An error is raised before any changes are saved to the record to avoid damaging any indexes.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE(message-num) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

- When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

- If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.
Example

The following example uses a browse widget to scan Customer records. Records within the browse are read with NO-LOCK. If you choose the Update Customer button, the CHOOSE trigger starts a transaction and applies an EXCLUSIVE-LOCK to the Customer record. When you have completed any updates, the procedure displays the new values in the browse widget and then executes a RELEASE statement. This ensures that the lock is released when the transaction ends.

If you omit the RELEASE statement in this example, the EXCLUSIVE-LOCK is downgraded to a SHARE-LOCK at the end of the transaction. This prevents other uses from updating that record. The SHARE-LOCK is released when you change the iteration of the browse.

Notes

- An ERROR occurs if the validation of the record fails. This can happen only with newly created records.
- If a record has been modified, the RELEASE statement causes a WRITE event and fires any related WRITE trigger to execute. All WRITE triggers execute before the record is actually written. If a WRITE trigger fails (or executes a RETURN statement with the ERROR option), the corresponding record is not written or released and the ERROR condition is raised for the RELEASE statement.
• See OpenEdge Getting Started: ABL Essentials for more information on transactions.

**RELEASE EXTERNAL statement**

Frees (that is, unloads from memory) a dynamic link library (DLL) or UNIX shared library.

**Syntax**

```
RELEASE EXTERNAL [ PROCEDURE ] "dll-name"
```

[ PROCEDURE ]

An optional “noise” keyword that does not affect the statement’s behavior in any way.

`dll-name`

A character string representing the name of the DLL or UNIX shared library.

**Example**

To free the DLL, mystuff.dll, code the following statement:

```
RELEASE EXTERNAL PROCEDURE "mystuff.dll".
```

**RELEASE OBJECT statement**

Releases the specified COM object (Automation object or ActiveX control) and removes all internal structures associated with the handle to the object.

**Syntax**

```
RELEASE OBJECT COM-hdl-var [ NO-ERROR ]
```

`COM-hdl-var`

A COM-HANDLE variable that references a valid COM object.

**NO-ERROR**

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

• Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.
• Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

• Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

• NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

• A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.

• When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

• If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

Example

This procedure fragment shows a control named hc_CmdButton being loaded into a control-frame and the handle to the control (controlHdl) being obtained using the control name (hc_CmdButton) property. Later, it releases the control and deletes the parent control-frame widget (CFWidHdl).
REPEAT statement

Begins a block of statements that are processed repeatedly until the block ends in one of several ways. Use an END statement to end a REPEAT block.

For an example of the RELEASE OBJECT statement applied to Automation objects, see the CREATE automation object statement entry.

Notes

- After this statement completes, any other component handles that reference the object are invalid. If you attempt to reference the object using one of these handles, the AVM returns an invalid handle error. It is also possible for a newly instantiated COM object to get the same handle as one that has been released. The AVM does not detect that this occurs. In this case, the “old” handle is valid, but it references a different control. Thus, it is a good practice to set any COM-HANDLE variables that reference a released COM object to the Unknown value (??).

- The released COM object remains active as long as any other COM object has a valid reference to it. In the case of an ActiveX control, the parent control-frame is a COM object that references the control. All other component handle references you establish in the ABL session represent a second reference to the COM object. Thus, when you release one of these component handles, the released COM object remains active as long as the parent control-frame COM object is still active. To release the parent control-frame COM object and complete the release of the ActiveX control, you must follow any release of the ActiveX control by a delete of the parent control-frame widget.

- When you delete a control-frame widget, the AVM releases all associated ActiveX controls automatically, whether or not you release them individually.

- When the session ends, the AVM automatically releases any active COM objects you have not released individually.

REPEAT statement

DEFINE VARIABLE CFwIdHdl1 AS HANDLE NO-UNDO.
DEFINE VARIABLE CFComHdl1 AS COM-HANDLE NO-UNDO.
DEFINE VARIABLE controlHdl1 AS COM-HANDLE NO-UNDO.

/* Create frame foo ... */
CREATE CONTROL-FRAME CFwIdHdl1 ASSIGN
  FRAME = FRAME Foo:HANDLE
  NAME  = "ctlFrame1".

CFComHdl1 = CFwIdHdl1:COM-HANDLE.
CFComHdl1:LoadControls(hc_CmdButton.wrx, "hc_CmdButton").

controlHdl1 = CFComHdl1:hc_CmdButton.
controlHdl1:BgColor = RGB-VALUE(0,128,0).

/* Do some more stuff ... WAIT-FOR ... */
RELEASE OBJECT controlHdl1. /* NOTE: Not really necessary */
DELETE WIDGET CFwIdHdl1.
Block properties

Iteration, record scoping, frame scoping, transactions by default.

Syntax

```
[ label : ]
REPEAT
 [ FOR record [, record ] ... ]
 [ preselect-phrase ]
 [ query-tuning-phrase ]
 [ variable = expression1 TO expression2 [ BY k ] ]
 [ WHILE expression ]
 [ TRANSACTION ]
 [ STOP-AFTER expression ]
 [ on-endkey-phrase ]
 [ on-error-phrase ]
 [ on-quit-phrase ]
 [ on-stop-phrase ]
 [ frame-phrase ]
 [ catch-block [ catch-block ... ] ]
 [ finally-block ] :
 repeat-body
```

FOR record [, record ] ... . . .

Names a record buffer and scopes the buffer to the block. The scope of a record determines when the buffer is cleared and the record is written back to the database. See OpenEdge Getting Started: ABL Essentials for more information on record scoping and blocks.

To access a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.

**preselect-phrase**

Goes through a table to select the records that meet the criteria you specify in a record-phrase. PRESELECT creates a temporary index that contains pointers to each of the preselected records in the database table. You can then use other statements, such as FIND NEXT, to process those records. Following is the syntax for preselect-phrase:

Syntax

```
PRESELECT
 [ EACH | FIRST | LAST ] record-phrase
 [ , { EACH | FIRST | LAST } record-phrase ] ... 
 [ [ [ BREAK ] { BY expression [ DESCENDING ] } ] ... ]
```

For more information, see the PRESELECT phrase reference entry.
REPEAT statement

query-tuning-phrase

Allows programmatic control over the execution of a DataServer query. Following is the syntax for the query-tuning-phrase:

Syntax

<table>
<thead>
<tr>
<th>QUERY-TUNING</th>
</tr>
</thead>
<tbody>
<tr>
<td>(</td>
</tr>
<tr>
<td>[ BIND-WHERE</td>
</tr>
<tr>
<td>[ CACHE-SIZE integer ]</td>
</tr>
<tr>
<td>[ DEBUG { SQL</td>
</tr>
<tr>
<td>[ INDEX-HINT</td>
</tr>
<tr>
<td>[ JOIN-BY-SQLDB</td>
</tr>
<tr>
<td>[ LOOKAHEAD</td>
</tr>
<tr>
<td>[ SEPARATE-CONNECTION</td>
</tr>
<tr>
<td>)</td>
</tr>
</tbody>
</table>

For more information, see the OpenEdge DataServer Guides (OpenEdge Data Management: DataServer for Microsoft SQL Server, OpenEdge Data Management: DataServer for ODBC, and OpenEdge Data Management: DataServer for Oracle).

variable = expression1 TO expression2 [ BY k ]

Indicates the name of a field or variable whose value you are incrementing in a loop. The expression1 is the starting value for variable on the first iteration of the loop. The k is the amount to add to variable after each iteration and must be a constant. When variable exceeds expression2 (or is less than expression2 if k is negative), the loop ends. Because expression1 is compared to expression2 at the start of the first iteration of the block, the block can be executed zero times. The expression2 is reevaluated with each iteration of the block.

WHILE expression

Indicates the condition during which the REPEAT block processes the statements within it. The block iterates as long as the condition specified by the expression is TRUE. The expression is any combination of constants, field names, and variable names that yield a logical value.

TRANSACTION

Identifies the REPEAT block as a system transaction block. The AVM starts a system transaction for each iteration of a transaction block if there is no active system transaction. See OpenEdge Getting Started: ABL Essentials for more information on transactions.

STOP-AFTER expression

The STOP-AFTER phrase specifies a time-out value for a DO, FOR, or REPEAT block. The integer expression specifies the number of seconds each iteration of a block has until a time-out occurs. If a time-out occurs, the AVM raises the STOP condition and default STOP condition handling occurs. Use an ON STOP phrase on the block (or an enclosing block) to alter the default STOP condition handling.

If the block iteration completes before the specified time expires, the timer resets to expression for the next iteration. In other words, the timer is limited to the scope of a
single block iteration. If a block with a STOP-AFTER phrase encloses another block or
calls another block, the timer continues while the inner blocks execute.

If a block with a STOP-AFTER phrase contains a nested block with a STOP-AFTER
phrase, then each has a timer in effect. If the outer block timer expires while the inner
block is executing, the STOP condition is raised even if the timer for the inner block has
not expired.

If the STOP condition is handled and execution resumes within the scope of a block with
a STOP-AFTER phrase, no timer is in effect until the next iteration of a block with a
STOP-AFTER phrase. In other words, all old timers are dismissed but new timers can now
be established.

When the timer expires, the STOP condition is raised on the current statement.

Two important use cases for the STOP-AFTER phrase are to time-limit dynamic queries
and to time-limit a procedure call. The following example time-limits a procedure call
using a RUN statement:

DEFINE VARIABLE cnt as INTEGER INITIAL 0.
PROCEDURE bumpCnt:
  cnt = cnt + 1.
END.
DO STOP-AFTER 5:
  RUN bumpCnt.
END.

Use this technique to also make timed calls to class methods and user-defined functions.

The following example is simplified code that lets you try different STOP-AFTER cases.

DEFINE VARIABLE EndlessCount AS INTEGER INITIAL 0.
DO STOP-AFTER 5 ON STOP UNDO, LEAVE:
  FOR EACH Customer STOP-AFTER 1:
    ASSIGN EndlessCount = EndlessCount + 1.
    /* Try a complex operation on a Customer record to use up the
timer in a single iteration and raise the STOP condition in the
inner block */
  END.
  MESSAGE "Procedure half complete. Endlesscount = " EndlessCount ".".
  REPEAT STOP-AFTER 1:
    ASSIGN EndlessCount = EndlessCount + 1.
    /*IF EndlessCount > 2000 THEN LEAVE. */
  END.
  MESSAGE "Procedure nearly complete. Endlesscount = " EndlessCount ".".
END.
MESSAGE "Procedure complete. Endlesscount = " EndlessCount ".".
If you run this code as is, the outer DO block establishes a 5 second time limit for the work of the DO block and all inner blocks. When the inner FOR EACH block starts, another timer is established for the first iteration of this block. When the first FOR EACH iteration completes, its timer is reset to 1 second for the next iteration. Meanwhile, the outer timer on the DO block continues without interruption.

The FOR EACH block completes and execution continues forward to the REPEAT block, which is an endless loop. The REPEAT block also has a 1 second timer for each iteration of the block. At some point, the outer 5 second timer elapses and the AVM raises the STOP condition. The STOP condition is raised on the statement the AVM was executing when the timer elapsed. Normal STOP handling proceeds from that point.

As the stack unwinds during STOP processing, the AVM encounters the ON STOP phrase on the DO block. The ON STOP phrase dismisses the STOP condition and resumes normal execution with the next statement following the DO block, as directed by the LEAVE option.

If you remove the comments from the IF statement in the REPEAT block, the block will complete within the outer time limit and the STOP condition is not raised.

If you want to experiment with elapsed timers on an inner block, insert a complex operation inside the FOR EACH block.

In the following example, the STOP-AFTER expression is modified during program execution:

```plaintext
DEFINE VARIABLE ix AS INTEGER NO-UNDO.
DEFINE VARIABLE stopTime AS INTEGER NO-UNDO INITIAL 30.

DO WHILE TRUE STOP-AFTER stopTime ON STOP UNDO, LEAVE:
    RUN spinHere (10000).
    stopTime = stopTime / 2.
END.
MESSAGE "program finished".

PROCEDURE spinHere:
    DEFINE INPUT PARAMETER spinLimit AS INT64 NO-UNDO.

    DEFINE VARIABLE endTime AS INT64 NO-UNDO.
    DEFINE VARIABLE loopFlag AS LOGICAL NO-UNDO.

    ASSIGN
        loopFlag = TRUE
        endTime = ETIME(FALSE) + spinLimit.

    DO WHILE loopFlag:
        IF (ETIME(FALSE) > endTime) THEN
            loopFlag = FALSE.
        END.
    END.
END PROCEDURE.
```

Because the STOP-AFTER expression is re-evaluated for each iteration of a looping block, any changes made to the expression during the iteration affect the timer for the block. In the example, the STOP-AFTER time limit is specified by the variable stopTime, which is initially set to 30 seconds. The procedure contains an iterating block which runs a procedure that executes for 10 seconds.
On the first iteration of the \texttt{DO WHILE TRUE} loop, \texttt{stopTime} is 30 seconds. The loop executes for 10 seconds, and then divides \texttt{stopTime} by 2. On the second iteration, the \texttt{stopTime} is 15 seconds; again the loop executes for 10 seconds, and then divides \texttt{stopTime} by 2. On the third iteration, the \texttt{stopTime} is 8 seconds. This time, the procedure \texttt{spinHere} runs for 8 seconds and then raises \texttt{STOP}. The \texttt{STOP} condition is handled by the \texttt{DO} block, and then the program displays the message \texttt{program finished}.

If a code block is called with a time limit of zero, the block is executed as if the \texttt{STOP-AFTER} phrase was omitted from the block declaration.

Consider the following example:

define variable barLimit as integer no-undo.
define variable ix as integer no-undo initial 1.
do stop-after 10 on stop undo, leave:
  run foo.
end.

procedure foo:
  run bar.
end procedure.

procedure bar:
  do while ix > 0 stop-after barLimit:
    ix = ix + 1.
  end.
end procedure.

In this example, procedure \texttt{foo} is run from within a timed block with a 10 second time limit; procedure \texttt{bar} is called from within the timed block, and contains an iterating block that specifies the \texttt{STOP-AFTER} phrase. Because the value of the \texttt{STOP-AFTER} expression evaluates to zero (that is, the current value of the \texttt{barLimit} variable), the block within \texttt{bar} is executed as an untimed block. However, the rules for execution of an untimed block within a timed block apply, so the untimed block in \texttt{bar} is executed with an implicit iteration time limit of 10 seconds.

Other points to consider are:

- If the expression evaluates to zero or less, then this is the equivalent of not specifying a \texttt{STOP-AFTER} phrase.

- \texttt{STOP-AFTER} phrases are not intended to interact with user interfaces.

- Blocking calls to third party software components, where the AVM has transferred execution control, cannot be timed out. This category includes operating system calls, MS Windows system calls, and calls to any third party DLLs and Unix shared objects.

\textit{on-endkey-phrase}

Describes the processing that takes place when the ENDKEY condition occurs during a block. Following is the syntax for the ON ENDKEY phrase:
### Syntax

**ON ENDKEY UNDO**

```
[ label1 ]
[ , LEAVE [ label2 ]
[ , NEXT [ label2 ]
[ , RETRY [ label1 ]
[ , RETURN [ return-value |
  ERROR [ return-value | error-object-expression ] ] |
  NO-APPLY ]
```

For more information, see the **ON ENDKEY phrase** reference entry.

**on-error-phrase**

Describes the processing that takes place when there is an error during a block. This is the syntax for the ON ERROR phrase:

```
ON ERROR UNDO
[ label1 ]
[ , LEAVE [ label2 ]
[ , NEXT [ label2 ]
[ , RETRY [ label1 ]
[ , RETURN [ return-value |
  ERROR [ return-value | error-object-expression ] ] |
  NO-APPLY ]
[ , THROW ]
```

For more information, see the **ON ERROR phrase** reference entry.

**on-quit-phrase**

Describes the processing that takes place when a QUIT statement is executed during a block. This is the syntax for the ON QUIT phrase:

```
ON QUIT
[ UNDO [ label1 ] ]
[ , LEAVE [ label2 ]
[ , NEXT [ label2 ]
[ , RETRY [ label1 ]
[ , RETURN [ return-value |
  ERROR [ return-value | error-object-expression ] ] |
  NO-APPLY ]
```

For more information, see the **ON QUIT phrase** reference entry.
**on-stop-phrase**

Describes the processing that takes place when the STOP conditions occurs during a block. This is the syntax for the ON STOP phrase:

**Syntax**

```
ON STOP UNDO 
[ label1 ] 
[ , LEAVE [ label2 ] ] 
| , NEXT [ label2 ] 
| , RETRY [ label1 ] 
| , RETURN [ return-value ] 
| ERROR [ return-value | error-object-expression ] | 
| NO-APPLY ] 
]
```

For more information, see the ON STOP phrase reference entry.

**frame-phrase**

Specifies the overall layout and processing properties of a frame. For more information, see the Frame phrase reference entry.

**repeat-body**

The body of the REPEAT block. Define repeat-body using the following syntax:

**Syntax**

```
repeat-logic

[ catch-block [ catch-block ... ] ]

[ finally-block ]

END .
```

**repeat-logic**

The logic of the REPEAT block. This logic can contain the ABL statements allowed within the routine-level block (e.g., procedure, user-defined, or method) where the REPEAT statement is defined.

Each logic statement must end with a period.

**catch-block**

Specifies a CATCH statement that defines error handling code for one or more error types. For more information on catch-block, see the CATCH statement reference entry.
finally-block

Specifies a FINALLY statement that defines the processing that must occur after all other processing in the block occurs. For more information on finally-block, see the FINALLY statement reference entry.

END

Specifies the end of the REPEAT block definition. You must end the REPEAT block definition with the END statement.

Example

In this menu procedure, if you press END-ERROR or ENDKEY when the procedure prompts you for your menu selection, any data you have entered as a selection is undone and the procedure continues to prompt you for a menu selection:

r-rpt.p

```as
DEFINE VARIABLE Selection AS INTEGER NO-UNDO FORMAT "9".

FORM SKIP(3)
"0 - Exit" at 32
"1 - Edit Customer File" at 32
"2 - List Customer File" at 32
"3 - Edit Item File" at 32
"4 - List Item File" at 32
"Enter Choice" TO 30 Selection AUTO-RETURN
HEADER "Application Name" "Master Menu" AT 34 "Company" TO 79
WITH NO-BOX NO-LABELS CENTERED FRAME menu.

/* Create the procedures that are called from the following block. */
REPEAT ON ENDKEY UNDO, RETRY:
  UPDATE Selection WITH FRAME menu.
  HIDE FRAME menu.
  CASE(Selection):
    WHEN 0 THEN LEAVE.
    WHEN 1 THEN RUN custedit.p.
    WHEN 2 THEN RUN custrpt.p.
    WHEN 3 THEN RUN itemedit.p.
    WHEN 4 THEN RUN itemrpt.p.
    OTHERWISE DO:
      BELL.
      MESSAGE "Not a valid choice. Try again."
    END.
  END CASE.
END. /* REPEAT */
```

Notes

- Within a REPEAT block, if you are using the FIND NEXT or FIND PREV statement and you change the value of an index field, the AVM makes that change in the index table at the end of the UPDATE or SET statement. Therefore, if you change the value so that the record appears later in the index table, you will see the record again if you FIND NEXT. If you change the value so that the record appears earlier in the index table, you see the record again if you FIND PREV.
In this example, if you change Customer 1 to Customer 300, you see that Customer record again at the end of the procedure.

When you use the PRESELECT option, the AVM builds a special index table that is not updated when index values change. For example, add the PRESELECT option to the previous example:

```
REPEAT PRESELECT EACH Customer:
   FIND NEXT Customer.
   UPDATE Customer.CustNum.
END.
```

In this example, if you change Customer 2 to Customer 200, you do not see that Customer record until you look it up with a new procedure.

- For SpeedScript, the invalid options are: `on-endkey-phrase` and `on-quit-phrase`.

**See also**

CATCH statement, DO statement, END statement, FINALLY statement, Frame phrase, ON ENDKEY phrase, ON ERROR phrase, ON QUIT phrase, ON STOP phrase

---

**REPLACE function**

Returns a string with specified substring replacements.

**Syntax**

```
REPLACE ( source-string, from-string, to-string )
```

*source-string*

Specifies the base string to make replacements in. The `source-string` parameter can be any expression that evaluates to a string or a LONGCHAR. The REPLACE function does not change the value of `source-string` itself; the function returns the string with replacements.

*from-string*

Specifies the substring to replace. The `from-string` parameter can be any expression that evaluates to a string or a LONGCHAR. Each occurrence of `from-string` within `source-string` is replaced.

*to-string*

Specifies the replacement substring. The `to-string` parameter can be any expression that evaluates to a string or a LONGCHAR. Each occurrence of `from-string` in `source-string` is replaced by `to-string`.

**Example**

The following example uses the REPLACE function to replace the string “user” with an actual user ID, if available:
r-repl.p

```lisp
DEFINE VARIABLE greeting AS CHARACTER NO-UNDO FORMAT "x(40)"
INITIAL "Starting user's session . . . .".

IF USERID("DICTDB") < > "" THEN
  greeting = REPLACE(greeting, "user", USERID("DICTDB")).
DISPLAY greeting WITH NO-LABELS.
```

Notes

- The REPLACE function replaces all occurrences of `from-string` within `source-string`. After replacing a substring, the REPLACE function resumes searching the string after the inserted text. Thus, the inserted text is not recursively searched (in whole or in part) for `from-string`.

- The search for occurrences of `from-string` within `source-string` is not case sensitive, unless one of the three values used in the function (`source-string`, `to-string`, or `from-string`) is a case-sensitive field or variable.

OVERLAY statement, SUBSTITUTE function, SUBSTRING function

REPOSITION statement

Repositions the cursor associated with a specific query. The query must be associated with a browse widget or defined with the SCROLLING option. The next record to be retrieved is the record following the cursor position.

Syntax

```lisp
REPOSITION query
  { TO ROWID rowid1 [, rowid2 ] ... [ NO-ERROR ]
    | TO RECID recid [ NO-ERROR ]
    | ROW n
    | FORWARDS n
    | BACKWARDS n
  }
```

query

The name of the query to reposition. The query must be open.

TO ROWID rowid1 [, rowid2 ] ... [ NO-ERROR ]

Repositions the query to the join levels that correspond to the rowids you specify. `rowid1` represents the rowid of the top level of join, `rowid2` represents the rowid of the next level of join, etc. You can specify any number of rowids up to the number of join levels. If you specify fewer rowids than the number of join levels, the AVM still repositions the query to the join levels that correspond to the rowids you specify, but arranges the remaining join levels arbitrarily.

NO-ERROR suppresses any error messages that result from specifying an illegal value or a value that does not identify any records returned by the query. See the NO-ERROR entry below for more information.
TO RECID recid [ NO-ERROR ]

Similar to the TO ROWID option, except that the value recid is an expression that evaluates to a RECID value, and you can specify only one recid. Supported only for backward compatibility.

NO-ERROR suppresses any error messages that result from specifying an illegal value or a value that does not identify any records returned by the query. See the NO-ERROR entry below for more information.

NO-ERROR

Suppresses ABL errors or error messages that would otherwise occur and diverts them to the ERROR-STATUS system handle. If an error occurs, the action of the statement is not done and execution continues with the next statement. If the statement fails, any persistent side-effects of the statement are backed out. If the statement includes an expression that contains other executable elements, like methods, the work performed by these elements may or may not be done, depending on the order the AVM resolves the expression elements and the occurrence of the error.

To check for errors after a statement that uses the NO-ERROR option:

- Check the ERROR-STATUS:ERROR attribute to see if the AVM raised the ERROR condition.

- Check if the ERROR-STATUS:NUM-MESSAGES attribute is greater than zero to see if the AVM generated error messages. ABL handle methods used in a block without a CATCH end block treat errors as warnings and do not raise ERROR, do not set the ERROR-STATUS:ERROR attribute, but do add messages to the ERROR-STATUS system handle. Therefore, this test is the better test for code using handle methods without CATCH end blocks. ABL handle methods used in a block with a CATCH end block raise ERROR and add messages to the error object generated by the AVM. In this case, the AVM does not update the ERROR-STATUS system handle.

- Use ERROR-STATUS:GET-MESSAGE( message-num ) to retrieve a particular message, where message-num is 1 for the first message.

If the statement does not include the NO-ERROR option, you can use a CATCH end block to handle errors raised by the statement.

Some other important usage notes on the NO-ERROR option:

- NO-ERROR does not suppress errors that raise the STOP or QUIT condition.

- A CATCH statement, which introduces a CATCH end block, is analogous to a NO-ERROR option in that it also suppresses errors, but it does so for an entire block of code. It is different in that the error messages are contained in a class-based error object (generated by the AVM or explicitly thrown), as opposed to the ERROR-STATUS system handle. Also, if errors raised in the block are not handled by a compatible CATCH block, ON ERROR phrase, or UNDO statement, then the error is not suppressed, but handled with the default error processing for that block type.
• When a statement contains the NO-ERROR option and resides in a block with a CATCH end block, the NO-ERROR option takes precedence over the CATCH block. That is, an error raised on the statement with the NO-ERROR option will not be handled by a compatible CATCH end block. The error is redirected to the ERROR-STATUS system handle as normal.

• If an error object is thrown to a statement that includes the NO-ERROR option, then the information and messages in the error object will be used to set the ERROR-STATUS system handle. This interoperability feature is important for those integrating code that uses the traditional NO-ERROR technique with the newer, structured error handling that features error objects and CATCH end blocks.

TO ROW n
Repositions the cursor to before the specified row in the result list of the query. The value n must be an integer expression that identifies a row in the result list. You cannot use this option with a query opened with the INDEXED-REPOSITION option.

FORWARDS n
Moves the cursor from its current position in the result list to a new position n records forward, where n represents an integer expression.

REPOSITION FORWARDS always places the cursor between two rows. For example:

• If the cursor is on a row—say, row 5—REPOSITION FORWARDS 1 moves the cursor to row 6, then to half way between rows 6 and 7. From this position, GET PREVIOUS moves the cursor to row 6, while GET-NEXT moves the cursor to row 7.

• If the cursor is already between two rows—say, between rows 5 and 6—REPOSITION FORWARDS 1 moves the cursor to half way between rows 6 and 7. From this position, GET PREVIOUS moves the cursor to row 6, while GET-NEXT moves the cursor to row 7.

BACKWARDS n
Moves the cursor from its current position in the result list to a new position n records back, where n represents an integer expression.

REPOSITION BACKWARDS always places the cursor between two rows. For example:

• If the cursor is on a row—say, row 5—REPOSITION BACKWARDS 1 moves the cursor to row 4, then to half way between rows 4 and 5. From this position, GET PREVIOUS moves the cursor to row 4, while GET-NEXT moves the cursor to row 5.

• If the cursor is already between two rows—say, between rows 5 and 6—REPOSITION BACKWARDS 1 moves the cursor to half way between rows 4 and 5. From this position, GET PREVIOUS moves the cursor to row 4, while GET-NEXT moves the cursor to row 5.

Example
The following example uses the REPOSITION statement to move forward or backward within a query:
REPOSITION statement

**Notes**

- The REPOSITION statement does not fetch a record, except when the query is associated with a browse. The REPOSITION statement positions the cursor for the query so that a subsequent GET NEXT statement fetches the specified record, and GET PREV fetches the record before it.

- After executing a REPOSITION statement that involves a multi-table join, the bottom-most buffer will not be available, as is the case for a query built on a single table. You then need to execute a GET NEXT statement to make the row you want available. The availability of non-bottom level buffers following the REPOSITION, however, is undetermined. That is, non-bottom level buffers may or may not be available.

- If you reposition a query associated with a browse widget, the browse widget data is refreshed with the record after the new position at the top.

- If you try to position the cursor outside the list of records that satisfy the query, the AVM does not raise the ERROR condition. If you try to position the cursor before the first record, the AVM positions the query to just before the first record. If you try to position the cursor beyond the last record, the AVM positions it just beyond the last record.
The REPOSITION statement might be slow if the record you position to has not yet been fetched.

The REPOSITION TO ROWID statement might be especially slow. If the record has not yet been fetched, the AVM performs a series of GET NEXT operations until the record is found. You can optimize the performance of a REPOSITION TO ROWID statement by opening the query using the INDEXED-REPOSITION option of the OPEN QUERY statement.

The INDEXED-REPOSITION option of the OPEN QUERY statement, followed by REPOSITION TO ROWID or GET LAST, causes the query results list to change dramatically. Subsequent use of the CURRENT-RESULT-ROW or NUM-RESULTS functions might produce unknown or unexpected results.

The order of the records in the query is determined by the options specified in the OPEN QUERY statement.

For SpeedScript, the on-endkey-phrase and the on-quit-phrase do not apply.

See also CLOSE QUERY statement, CURRENT-RESULT-ROW function, DEFINE QUERY statement, GET statement, NUM-RESULTS function, OPEN QUERY statement

---

**RETRY function**

Returns a TRUE value if the current block is being reprocessed after a previous UNDO, RETRY.

**Syntax**

```plaintext
RETRY
```

**Example**

This procedure bypasses the display of the Customer data when the REPEAT block is retried (if user changes the Customer data and does not specify a country). When you run this procedure, notice that even though the procedure has undone any data that you entered (if you did not specify a country), the data still appears in the window. The data is saved in the screen buffers, but it is not stored in the Customer record buffer. If you do not use the RETRY function, the AVM reprocesses the DISPLAY statement and displays the previous values for the Customer fields, overwriting the data that was entered in error.

```plaintext
r-retry.p

REPEAT:
  PROMPT-FOR Customer.CustNum.
  FIND Customer USING Customer.CustNum.

  IF NOT RETRY THEN
  ELSE

  IF Customer.Country = "" THEN UNDO, RETRY.
END.
```
RETURN statement

Leaves the local or remote procedure or user-defined function block, trigger block, database trigger block, the method block of a class, the class constructor block, or the property accessor block, and returns to the calling procedure, user-defined function, method, constructor, or property accessor. If there is no caller, RETURN returns to the Procedure Editor or other ADE or OpenEdge Architect tool that invoked the procedure, user-defined function, trigger block, database trigger, class-based method, constructor, or property accessor.

For more information on remote procedures, see OpenEdge Application Server: Developing AppServer Applications.

Syntax

```
RETURN [ return-value | ERROR [ return-value | error-object-expression ] | NO-APPLY ]
```

*return-value*

The value that RETURN returns to the caller, with or without the ERROR condition:

- **Without the ERROR condition** — In a procedure or trigger block, the optional *return-value* must be a CHARACTER expression. If you do not specify *return-value* in a procedure or trigger block, *return-value* is returned as the empty string (""). In a VOID method, you cannot set a *return-value*. In a user-defined function or in a method of a class that returns a value (non-VOID), *return-value* must be specified and must be an expression whose data type matches the return type of the function or method; data type matching between the expression and return type follows the data type widening rules for an expression passed to an OUTPUT parameter (see the Parameter passing syntax reference entry for more information).

- **With the ERROR condition** — In a method of a class (VOID or non-VOID), a constructor, a property accessor, a user-defined function, a procedure, or a database trigger block, the optional *return-value* must be a CHARACTER expression. If you do not specify either *return-value* or *error-object-expression* (see the ERROR option), *return-value* is returned as the empty string (""").

For more information on how the caller can access *return-value* in each case, see the ERROR option.

Notes

- Using the RETRY function in a block turns off the default error processing, which result in no infinite loop protection for the block.

- For more information on retry processing, see OpenEdge Getting Started: ABL Essentials.

See also

UNDO statement
RETURN statement

ERROR

Causes an ERROR condition in the calling block. This can cause the ERROR condition to be raised for the following statements in the caller:

- The RUN statement for a procedure
- Any statement that invokes a user-defined function
- Any statement that invokes a method of a class
- Any statement that invokes the NEW function (classes) to instantiate a class (invoking the specified constructor and all other constructors for the class hierarchy)
- Any statement that accesses a property defined with a property accessor

You can use the ERROR option in a procedure, database trigger block, class-based method, constructor, property accessor method, or user-defined function. However, you cannot use the ERROR option in a user-interface trigger block to raise ERROR outside of the trigger block. Any values that are set for OUTPUT or INPUT-OUTPUT parameters before the RETURN ERROR executes are not returned to the caller.

If return-value is specified, the ABL Virtual Machine (AVM) automatically generates a Progress.Lang.AppError that the caller can obtain using a CATCH statement and obtain return-value from the ReturnValue property of the AppError. If no return-value or error-object-expression is specified, the AVM also generates an AppError with its ReturnValue property set to the empty string (""). The following table shows how to access return-value in the caller in various cases:

<table>
<thead>
<tr>
<th>In this case . . .</th>
<th>How to retrieve the return value in the caller . . .</th>
</tr>
</thead>
<tbody>
<tr>
<td>The return-value is specified without the ERROR option in a procedure or trigger block.</td>
<td>Access the RETURN-VALUE function.</td>
</tr>
<tr>
<td>The return-value is specified for a non-VOID method or user-defined function without the ERROR option.</td>
<td>In this case, the caller accesses the method or function return value by referencing the function or method call in an expression, similar to referencing a variable.</td>
</tr>
<tr>
<td>The return-value is specified with the ERROR option.</td>
<td>Access the RETURN-VALUE function, or CATCH the Progress.Lang.AppError object automatically created by the AVM and check the ReturnValue property of the AppError object. <strong>Note:</strong> User-defined functions have different behavior since they must return the data type specified in the definition. See the “FUNCTION statement” section on page 612 for more information.</td>
</tr>
<tr>
<td>The error-object-expression is specified</td>
<td>If error-object-expression is a Progress.Lang.AppError, CATCH the specified error object and access its ReturnValue property, or access the RETURN-VALUE function.</td>
</tr>
</tbody>
</table>
error-object-expression

An expression that resolves to a specific error object. It must be an object derived from Progress.Lang.ProError (you can only THROW error objects) or an object of a class that implements Progress.Lang.Error. It is a compile-time error to THROW an object that is not derived from Progress.Lang.ProError or Progress.Lang.Error. Note that the only error object that you can instantiate directly is a Progress.Lang.AppError object or a subclass.

Note: RETURN ERROR error-object-expression immediately returns to the caller before throwing the error object. Unlike a direct THROW, it ignores any CATCH blocks or ON ERROR directives in effect at the time of the RETURN.

NO-APPLY

Suppresses the default behavior for the current user-interface event. You thus can use the NO-APPLY option in a user-interface trigger block to suppress that behavior. For example, the default behavior for a character code key press in a fill-in field is to echo the character in the field. If you execute RETURN NO-APPLY in a trigger, this behavior is not performed. Also, NO-APPLY returns without setting a return-value or error object.

If you do not specify any options for the RETURN statement in a procedure or trigger block, return-value is returned as the empty string ("""). In a VOID method, you cannot specify any options except for the ERROR options, and RETURN without ERROR options returns without setting a return-value or error object.

Examples

The r-fact.p procedure is called recursively because (n factorial) is n * ((n - 1) factorial). The r-fact.p procedure first checks that the input value is valid. If the value is invalid, it returns a message to the caller. Note that r-return.p checks the ReturnValue property immediately after running r-fact.p. If a message is returned, r-return.p displays that message.

The procedure r-return.p accepts an integer as input and then runs r-fact.p to calculate the factorial of that integer. The factorial of a number is the result of multiplying together all of the integers less than or equal to that number (for example: 3 factorial is 3 * 2 * 1 = 6). The r-fact.p procedure is called recursively because n factorial is n * (n -1) factorial.
Note that this is not the most efficient way to calculate factorials, but in other applications, such as bill of material explosions, recursive procedures are very effective.
The **RETURN-VALUE** function provides the value returned by the most recently executed RETURN or THROW with options that set or clear a *return-value*.

If a procedure executing the RETURN statement is called asynchronously, the client can access the *return-value* and **ERROR** condition in the associated event procedure. For more information on event procedures, see *OpenEdge Application Server: Developing AppServer Applications*.

---

**RETURN-VALUE function**

Provides a character string value returned by the most recently executed RETURN statement of a local or remote procedure, trigger block, user-defined function, method of a class, class constructor, or property accessor.

**Syntax**

```
RETURN-VALUE
```

**Example**

For examples of the **RETURN-VALUE** function, see the **RETURN** statement reference entry.

**Notes**

- The returned value has the **CHARACTER** data type.

- When you access **RETURN-VALUE**, its value represents the value returned by the most recently executed RETURN or THROW:
  - If it is a RETURN with options that can set the **RETURN-VALUE**, but does not, the empty string ("") is returned.
  - If it is a THROW that returns a **Progress.Lang.AppError** object, the value of the object’s ReturnValue property is returned.

- To reliably access a **RETURN-VALUE** setting returned from a block or called routine, check **RETURN-VALUE** as soon as you can after the block or called routine terminates.

- **RETURN-VALUE** does not return the value of a non-VOID method of a class or user-defined function invocation. You return the values of these methods and functions within an expression where you reference their invocations, similar to referencing a variable value.

- For more information on returning results from remote procedures, see *OpenEdge Application Server: Developing AppServer Applications*.

951
RGB-VALUE function

Returns an INTEGER value that represents a combination of a red, green, and blue color value. This function allows you to define an arbitrary color, expanding beyond those colors defined in the color table.

**Note:** Does not apply to SpeedScript programming.

**Syntax**

```
RGB-VALUE ( redval , greenval , blueval )
```

*redval*, *greenval*, *blueval*

Identifies red, green, and blue color values which can be combined to define a unique color value.

**Example**

The following code fragment shows how to set the background color of an ActiveX control:

```
DEFINE VARIABLE hdlControl AS COM-HANDLE NO-UNDO.
/* Complete code to get a handle to a control in a control-frame.*/
... hdlControl:BackColor = RGB(128, 0, 256).
```

For detailed information on programming ActiveX Controls, see *OpenEdge Development: Programming Interfaces* manual.

**Note**

The RGB-VALUE function is generally most useful when it is used with ActiveX Controls.

COLOR-TABLE system handle

---

**RIGHT-TRIM function**

Removes trailing white space, or other specified characters, from a CHARACTER or LONGCHAR expression.

**Syntax**

```
RIGHT-TRIM ( expression [ , trim-chars ] )
```

*expression*

An expression (a constant, field name, variable name, or expression) whose value is a CHARACTER or LONGCHAR. If *expression* is a case-sensitive variable, the AVM performs a case-sensitive trim. If *expression* is a LONGCHAR, the result is in the same code page.
trim-chars

A character expression that specifies the characters to trim from expression. If you do not specify trim-chars, the RIGHT-TRIM function removes spaces, tabs, line feeds, and carriage returns.

Example

The following example shows the effects of the TRIM, RIGHT-TRIM, and LEFT-TRIM functions:

r-ltrim.p

```
DEFINE VARIABLE ix  AS INTEGER NO-UNDO.
DEFINE VARIABLE txt AS CHARACTER NO-UNDO FORMAT "X(26)"
   INITIAL "***** This is a test *****".

DEFINE BUTTON b_left LABEL "Left Trim".
DEFINE BUTTON b_right LABEL "Right Trim".
DEFINE BUTTON b_trim LABEL "Trim".
DEFINE BUTTON b_quit LABEL "Quit" AUTO-ENDKEY.

DEFINE FRAME butt-frame
   txt ix LABEL "String Length" SKIP(2)
   b_left b_right b_trim b_quit
WITH CENTERED TITLE "Original Text String".

DEFINE FRAME trimed-frame
   txt LABEL "Trimed Text"
   ix LABEL "Length"
WITH CENTERED.

ON CHOOSE OF b_trim, b_right, b_left IN FRAME butt-frame DO:
   FRAME trimed-frame:TITLE  = "Data After " + SELF:LABEL.
   DISPLAY TRIM(txt, "* ") WHEN SELF:LABEL = "Trim" @ txt
   LENGTH(TRIM(txt, "* ")) WHEN SELF:LABEL = "Trim" @ ix
   LEFT-TRIM(txt,"* ") WHEN SELF:LABEL = "Left Trim" @ txt
   LENGTH(LEFT-TRIM(txt,"* ") WHEN SELF:LABEL = "Left Trim" @ ix
   RIGHT-TRIM(txt, "* ") WHEN SELF:LABEL = "Right Trim" @ txt
   LENGTH(RIGHT-TRIM(txt, "* ") WHEN SELF:LABEL = "Right Trim" @ ix
WITH FRAME trimed-frame.
END.

ENABLE b_left b_right b_trim b_quit WITH FRAME butt-frame.
ix = LENGTH(txt).
DISPLAY txt ix WITH FRAME butt-frame.

WAIT-FOR CHOOSE OF b_quit IN FRAME butt-frame.
```

Notes

- The RIGHT-TRIM function is similar to the TRIM function except that it trims characters only from the right end of the string.

- If expression is a case-sensitive field or variable, then trim-chars is also treated as case sensitive. Otherwise, trim-chars is not case sensitive.

- The RIGHT-TRIM function is double-byte enabled. The specified expression and trim-chars arguments can contain double-byte characters. RIGHT-TRIM does not remove double-byte space characters by default.

LEFT-TRIM function, TRIM function
ROUND function

Rounds a decimal expression to a specified number of places after the decimal point.

Syntax

```
ROUND ( expression , precision )
```

**expression**

A decimal expression.

**precision**

A non-negative integer expression whose value is the number of places you want in the decimal result of the ROUND function.

Example

This procedure increases all CreditLimit values by 10 percent, rounding those values to the nearest $100:

```
r-round.p
FOR EACH Customer:
    Customer.CreditLimit = ROUND((Customer.CreditLimit * 1.1) / 100 ,0) * 100.
    PAUSE.
    DISPLAY Customer.CreditLimit.
END.
```

TRUNCATE function

ROUTINE-LEVEL ON ERROR UNDO, THROW statement

Use this statement in a procedure (.p) or class (.cls) file to change the default ON ERROR phrase associated with routine-level blocks and ON blocks used as database triggers.

Syntax

```
ROUTINE-LEVEL ON ERROR UNDO, THROW.
```

The undoable blocks (DO, FOR, and REPEAT), support the ON ERROR UNDO, THROW phrase. This phrase is useful for propagating errors up the call stack where they can be handled by CATCH blocks associated with higher level blocks. This technique eliminates the need for CATCH blocks handling common error types at every level in a series of nested blocks.

The main blocks of ABL routines do not support explicit ON ERROR phrases. The following blocks are called routine-level blocks:

- Main block of an external procedure (.p)
- Internal procedure
- User-defined function
- Method of a class
• Class constructor

• Property accessor

The routine-level blocks have an implicit, default ON ERROR UNDO, RETRY phrase (with infinite loop protection). Therefore, you cannot change the default behavior for routine-level blocks to throw or re-throw errors with the ON ERROR phrase.

The ROUTINE-LEVEL ON ERROR UNDO, THROW statement for class (.cls) and procedure (.p) files changes the default implicit ON ERROR phrase to ON ERROR UNDO, THROW for every routine-level block contained in the file.

Similarly, when an ON block is a database trigger with a CREATE, DELETE, WRITE or ASSIGN event, the ROUTINE-LEVEL ON ERROR UNDO, THROW statement changes the implicit ON ERROR phrase to ON ERROR UNDO, THROW.

The following are rules affecting the placement of this statement:

• This statement must come before any definitional or executable statement in the procedure or class file.

• The statement can come before or after a USING statement.

Example
This block propagates an error from a DO block up to the main procedure block. A CATCH block on the main procedure block handles the error.

r-ROUTINE-LEVEL-01.p

```
ROUTINE-LEVEL ON ERROR UNDO, THROW.

PROCEDURE find1000:
    FIND FIRST Customer WHERE Customer.CustNum = 1000.
END PROCEDURE.

PROCEDURE find2000:
END PROCEDURE.

PROCEDURE find3000:
    FIND FIRST Customer WHERE Customer.CustNum = 3000.
END PROCEDURE.

/* Main Block */
RUN find1000.
RUN find2000.
RUN find3000.

CATCH eAnyError AS Progress.Lang.SysError:
    MESSAGE "Your CATCH block associated with the main block (.p) has handled an error in an internal procedure."
    VIEW-AS ALERT-BOX BUTTONS OK.
END CATCH.
```

Notes
• The term routine level should not be mistaken to imply that you can define a single CATCH block at the class or procedure file level that will handle an error type from any sub-procedure in a persistent procedure or method in a class. The statement simply alters default error handling behavior of all sub-procedures and methods within the file. For these “routine-level” blocks, the default error handing behavior is changed from ON ERROR UNDO, RETRY to ON ERROR UNDO, THROW. The ROUTINE-LEVEL ON
ERROR UNDO, THROW statement behavior guarantees that all unhandled errors in a sub-procedure of a persistent procedure or method of a class will be propagated up to the caller. You decide for each sub-procedure or method within the file whether that sub-procedure or method should handle errors locally with its own CATCH blocks. Alternatively, you may want to avoid local CATCH blocks and let the caller handle all errors with a CATCH block at the caller level. This can be useful if a caller calls many internal procedures in a persistent procedure or many methods in a class.

- This statement does not apply to destructors, since destructors cannot raise error in the caller. The statement has no effect on DO, FOR, or REPEAT blocks contained within the routine-level blocks. The statement has no effect on ON blocks that are UI triggers.
- When a routine-level block or a database trigger has a CATCH statement that explicitly handles the thrown error, then the CATCH block handles the error and it is not thrown up the call stack (unless the CATCH block rethrows it).

ON ENDKEY phrase, ON ERROR phrase, ON QUIT phrase, RETURN statement, RETURN-VALUE function, STOP statement

**ROW-STATE function**

Returns an INTEGER value that represents the current change state of a static ProDataSet temp-table buffer.

**Syntax**

```plaintext
ROW-STATE( buffer-name )
```

*buffer-name*

The name of a ProDataSet temp-table buffer (preferably a before-image temp-table buffer).

**Notes**

- The ROW-STATE function corresponds to the ROW-STATE attribute.
- When the TRACKING-CHANGES attribute is set to TRUE for a ProDataSet temp-table, the AVM tracks changes to the data in that temp-table using a before-image temp-table that contains the original version of each modified row. You can think of the temp-table itself as the after-image because it contains the latest version of each row.

Every row in the after-image table that has been modified or created corresponds to a row in the before-image table. Deleted rows do not appear in the after-image table, because it reflects the current state of the data. Every row in the before-image table has a non-zero ROW-STATE, because every row is the before-image of a deleted, created, or modified row in the after-image table. Unchanged rows do not appear in the before-image table.

You can use the ROW-STATE function on each row in either the after-image table or the before-image table to determine whether a row has changed and how it has changed.

- The possible return values can be expressed as compiler constants. Table 58 lists these values.
The ROW-STATE function returns the Unknown value (?) when the specified temp-table buffer:

- Does not contain a record
- Is an after-image table with no associated before-image table

You can invoke the ROW-STATE function from within a WHERE clause (unlike the corresponding attribute). For example:

```sql
WHERE ROW-STATE(ttOrder) = ROW-MODIFIED.
```

See also Buffer object handle. ROW-STATE attribute, TRACKING-CHANGES attribute

### ROWID function

Returns the unique internal identifier of the database record currently associated with the record buffer you name. This internal identifier has the data type ROWID, which is supported for OpenEdge and all other DataServer databases.

**Note:** The ROWID function corresponds to the ROWID attribute.

This function replaces the RECID function for most applications. However, you must use the RECID function for maintaining schema objects (file and field relationships) in the ABL meta-schema files.

#### Syntax

```sql
ROWID ( record )
```

*record*

The name of the record whose ROWID you want.

To use the ROWID function with a record in a table defined for multiple databases, you must qualify the record’s table name with the database name. See the Record phrase reference entry for more information.
Example

You might decide that you do not want to lock a record until the user starts to update that record. In the example procedure, the FIND statement reads a Customer record without locking the record. The ROWID function puts the internal database identifier of that record in the crowid variable. If the user decides to update the CreditLimit field, the procedure finds the record again using the value in crowid. The second FIND statement reads the record again, this time placing an EXCLUSIVE-LOCK on it. Because the record is first found with NO-LOCK, it is possible for the record to be updated by another user after the first FIND and before the second.

r-rowid.p

```abl
DEFINE VARIABLE response AS LOGICAL NO-UNDO.
DEFINE VARIABLE crowid AS ROWID NO-UNDO.

REPEAT:
  PROMPT-FOR Customer.CustNum.
  FIND Customer USING Customer.CustNum NO-LOCK.
  crowid = ROWID(Customer).
  DISPLAY Customer.Name.
  response = YES.
  UPDATE response LABEL "Update CreditLimit ?".
  IF response THEN DO:
    FIND Customer WHERE ROWID(Customer) = crowid EXCLUSIVE-LOCK.
    UPDATE Customer.CreditLimit.
  END.
END.
```

Notes

- Use the ROWID function to rapidly retrieve a previously identified record, even if that record has no unique index.

- The ROWID data type is a variable-length byte string capable of representing a record identifier for any DataServer database. However, the scope of a specific ROWID returned by the ROWID function depends on the DataServer and possibly the table within a database. The ROWID values for some DataServers change whenever the corresponding record is modified. For others, a ROWID value can change when a particular column in a table is modified. For more information on how different DataServers derive and work with ROWID values, see the OpenEdge DataServer Guides (OpenEdge Data Management: DataServer for Microsoft SQL Server, OpenEdge Data Management: DataServer for ODBC, and OpenEdge Data Management: DataServer for Oracle).

- You cannot return a ROWID for a view because view records do not have unique identifiers.

- You can compare ROWID values using the ABL relational operators (=, >, <, <=, and >=), such as in the WHERE option of the Record phrase.

- You can use a ROWID value in a REPOSITION statement to specify the new position for a query cursor.

- If you want a called procedure to use the same record as a calling procedure, use the ROWID function to ensure that you are retrieving the same record. Use a SHARED ROWID variable or procedure parameter to communicate the ROWID of a record from one procedure to another. The second procedure can then find the same record. This is an alternative to using shared buffers or buffer parameters.

- You can store a ROWID value in a work table, but not directly in a temp-table or database table. You can use the STRING function to convert a ROWID value to a character string,
which you can store in a temporary or database table, and convert it back to a ROWID value using the TO-ROWID function.

- You do not have to explicitly check to see whether a record is AVAILABLE before using the ROWID function. The ROWID function returns the Unknown value (?) if a record cannot be accessed.

This example checks the ROWID for each Customer record returned for a query to determine if another record exists to update. If no more records exist, the update loop (QuickFix) terminates.

```plaintext
OPEN QUERY qCustomer FOR EACH Customer

QuickFix:
REPEAT:
  GET NEXT qCustomer.
  IF ROWID(Customer) = ? THEN LEAVE QuickFix.
  ELSE UPDATE Customer.
END. /* QuickFix */
```

DEFINE BUFFER statement, DEFINE VARIABLE statement, RECID function, Record phrase, REPOSITION statement, STRING function, TO-ROWID function

### RUN statement

Calls an ABL procedure. This procedure can be local to or remote from the current session, external from or internal to the current procedure, and either synchronous or asynchronous. When a local or remote procedure is called synchronously, the calling procedure resumes execution only after the called procedure completes execution. When a remote procedure is called asynchronously, the calling procedure resumes execution immediately after the remote request is sent to the AppServer.

The RUN statement can also call functions or routines that reside in the Windows Dynamic Link Libraries (DLLs) or in UNIX shared libraries. The called routine must first be declared like an ABL internal procedure. The procedure declaration must be in the same file as the RUN statement.

You can also use the RUN statement to create and associate a procedure object with a Web service, and invoke a Web service operation.
Syntact

Use the following syntax to create and associate a procedure object with a Web service:

```plaintext
RUN { extern-proc-name
  | VALUE ( extern-expression )
  | path-name<member-name>
} [ PERSISTENT [ SET proc-handle ] ]
[ ON [ SERVER ] { server-handle | session-handle }]
[ TRANSACTION DISTINCT ]
[ ASYNCHRONOUS
  [ SET async-request-handle ]
  [ EVENT-PROCEDURE event-internal-procedure
    [ IN procedure-context ] ]
]
[ ( parameter [ , parameter ] ... ) ]
[ argument ] ...
[ NO-ERROR ]
```

Use the following syntax to invoke a Web service operation:

```plaintext
RUN intern-proc-name | VALUE ( intern-expression )
[ IN proc-handle ]
[ ASYNCHRONOUS
  [ SET async-request-handle ]
  [ EVENT-PROCEDURE event-internal-procedure
    [ IN procedure-context ] ]
]
[ ( parameter [ , parameter ] ... ) ]
[ argument ] ...
[ NO-ERROR ]
```

Use the following syntax to create and associate a procedure object with a Web service:

```plaintext
RUN portTypeName [ SET hPortType ] ON SERVER hWebService [ NO-ERROR ].
```

Use the following syntax to invoke a Web service operation:

```plaintext
RUN operationName IN hPortType
[ ASYNCHRONOUS
  [ SET async-request-handle ]
  [ EVENT-PROCEDURE event-internal-procedure
    [ IN procedure-context ] ]
  [ ( parameter [ , parameter ] ... ) ]
[ argument ] ...
[ NO-ERROR ].
```
**RUN statement**

`extern-proc-name`

The name of the (local or remote) external procedure to run. On UNIX, external procedure names are case sensitive; in Windows, they are not. If you specify a relative pathname, ABL searches the directories (and libraries, on platforms that support libraries) defined in the PROPATH environment variable. With `extern-proc-name`, you can specify a local or remote procedure.

**VALUE ( extern-expression )**

An expression that returns the name of the (local or remote) external procedure you want to run.
